ABBREVIATIONS

aq. = aqueous

atm. = atmospheric or atmosphere(s)

at. vol. = atomic volume(s)

at. wt. = atomic weight(s)

T° or $^\circ K$ = absolute degrees of temperature

b.p. = boiling point(s)

θ° = centigrade degrees of temperature

coeff. = coefficient

conc. = concentrated or concentration

dil. = dilute

eq. = equivalent(s)

f.p. = freezing point(s)

m.p. = melting point(s)

$\text{mol(s)} = \begin{cases} \text{gram-molecule(s)} \\ \text{gram-molecular} \end{cases}$

$\text{mol(s).} = \begin{cases} \text{molecule(s)} \\ \text{molecular} \end{cases}$

mol. ht. = molecular heat(s)

mol. vol. = molecular volume(s)

mol. wt. = molecular weight(s)

press. = pressure(s)

sat. = saturated

soln. = solution(s)

sp. gr. = specific gravity (gravities)

sp. ht. = specific heat(s)

sp. vol. = specific volume(s)

temp. = temperature(s)

vap. = vapour

In the **cross references** the first number in clarendon type is the number of the volume; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus **5**. 38, 24 refers to § 24, chapter 38, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, **49**. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances A, B, and C, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the

triangle represent the single components A, B, and C, the sides of the triangle represent binary mixtures of A and B, B and C, or C and A; and points within the triangle, ternary mixtures. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure A will be represented by a point at the apex marked A. If 100 be the
FIG. 1.   FIG. 2.   FIG. 3.

standard of reference, the point A represents 100 per cent. of A and nothing else; mixtures containing 80 per cent. of A are represented by a point on the line 88, 60 per cent. of A by a point on the line 66, etc. Similarly with B and C—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this
FIG. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point M represents a mixture containing 20 per cent. of A, 20 per cent. of B, and 60 per cent. of C.

CHAPTER LXIII

URANIUM

§ 1. The History of Uranium

THE black mineral called **pitchblende** from Joachimsthal in Bohemia and Johann-georgenstadt in the Erzgebirge of Saxony was recognized by the early mineralogists, but they were puzzled with its classification. In 1727, F. E. Brückmann [1] called it *Schwarz Beckerz*; J. G. Wallerius, *Beckblände*, or *pseudogalena picca*—that is, a pitchy zinc blende; and I. Eques a Born, *Pechblende*, or *pseudogalena nigra compacta*. J. G. Wallerius, I. Eques a Born, and M. T. Brünnich classed the mineral among the zinc ores; but A. G. Werner transferred it to the iron ores, and called it *Pech-blende*, or *Eisenpecherz*; and later, A. G. Werner suggested that the mineral might contain the metallic radical tungsten or wolfram. In August, 1786, M. H. Klaproth [2] read a paper: *Chemische Untersuchungen des Uranerzes*, in which he showed that the mineral partly dissolves in aqua regia, and that the cold, clear soln. when treated with alkalies deposits a yellow oxide. A soln. of the precipitated oxide in sulphuric acid gave crystals of a lemon-yellow sulphate; in nitric acid, crystals of greenish nitrate; in hydrochloric acid, yellowish-green crystals of the chloride; in vinegar, topaz-yellow crystals of the acetate; and in phosphoric acid, amorphous, yellowish-white flocculi of the phosphate. He thus proved that "the mineral does not belong to the ores of zinc, to those of iron, nor yet to those of tungsten or wolfram, and, in general, to none of the metallic substances hitherto known; but, on the contrary, it consists of an *eigenthumliche, selbständige, metallische Substanz.* Consequently, its former designations pitchblende, pitchironstone, etc., are no longer applicable, and must be replaced by another more appropriate name. I have chosen that of *uranite*, as a kind of memorial that the chemical discovery of this new element happened in the epoch of the astronomical discovery of the planet Uranus." At the beginning of his memoir M. H. Klaproth said:

The ancient philosophers, who considered our globe as the centre of the material universe; and the sun on the contrary, merely as a planet destined, like the others, to a periodical circumvolution round the earth, flattered themselves that they had discovered a great mystery of nature, in the agreement of the seven celestial bodies which they assumed for planets, with the seven metals known in those times. In consequence of the various hypotheses which they founded on this supposed mystery, they allotted to each metal a certain planet, by whose astral effluvia its generation and maturation were to be promoted. In like manner they took from these planets their names and symbols, to designate the metals subordinated to them. However, as the above number of metals has long since been increased by later researches; and as the discovery of new planets has not kept pace with that of metals, the metals newly discovered have been deprived of the honour of receiving their names from the planets, like the older ones.

M. H. Klaproth called the element **uranium**—after the planet Uranus, at that time the *dernier cri* of celestial exploration. J. G. Leonhardi [3] suggested naming it *klaprothium*, in honour of its discoverer. The etymology of the term uranium was discussed by P. Diergart, and H. von Freudenberg.

In 1789, M. H. Klaproth found uranium in *green mica*, the *mica viridis* of I. Eques a Born. A. G. Werner had named the mineral *torberite*—after Torber Bergman—or **torbernite**—the latinized form Torbernus as written by T. Bergman himself. Objections were raised to naming minerals after persons, and A. G. Werner

substituted the term *chalcolite*—from χαλκός, copper—signifying, as he said, a cupriferous mineral, in allusion to T. Bergman's analysis indicating that the mineral is muriated copper and clay. After M. H. Klaproth had shown that the mineral contains uranium and not copper as the dominant base, A. G. Werner, and D. L. G. Karsten dropped the term chalcolite, and called it *uranium mica—Uranglimmer*. M. H. Klaproth called it *uranites spathosus* ; A. Breithaupt, *uranphyllite*, and *cuprouranite* ; A. Aikin, *uranite* ; whilst W. H. Miller, and J. D. Dana kept the old term of A. G. Werner, *tobernite*.

M. H. Klaproth heated a mixture of yellow uranium oxide with a reducing agent, and obtained a black powder which he considered to be metallic uranium. He said :

> I triturated 120 grains of the yellow oxide to a paste with linseed oil, and caused the oil gently to burn on a sherd. There remained 85 grains of a heavy black powder which I exposed in a well-secured charcoal crucible to the medium heat of a porcelain kiln. . . . The metallized oxide of pitchblende forms a heavy, loosely coherent mass which by friction between the fingers can be divided into a dark brown powder possessed of a metallic lustre.

This result was confirmed by J. B. Richter,[4] C. F. Bucholz, A. Schönberg, L. R. Lecanu and M. Serbat, J. A. Arfvedson, and J. J. Berzelius between the years 1792 and 1823. This is strange. E. M. Péligot, in his *Recherches sur l'urane* (1841), pointed out that a mistake had been made. The supposed uranium was really the lowest oxide, UO_2—or possibly a mixture of that oxide with uranium—derived from yellow uranium oxide by reduction with carbon. E. M. Péligot obtained elemental uranium by reducing the tetrachloride with sodium. The history of uranium has been discussed by J. L. C. Zimmermann.[5]

§ 2. The Occurrence of Uranium

Uranium does not occur native, but it occurs in a few scarce minerals, and is sparsely distributed in the earth's crust. According to F. W. Clarke and H. S. Washington,[1] the average proportion of uranium in the igneous rocks of the earth's crust is 8×10^{-5} per cent. ; J. H. L. Vogt estimated $n \times 10^{-8}$ per cent. They added that, in general, uranium is nearly as abundant as copper. W. Vernadsky gave $0 \cdot 0_5 3$ per cent. for the proportion of uranium, and $0 \cdot 0_4 5$ for the atomic proportion of uranium in the earth's crust. W. and J. Noddack and O. Berg gave 7×10^{-8} for the absolute abundance of uranium in the earth's crust. The general subject was discussed by H. S. Washington, W. Lindgren, G. Tammann, E. Herlinger, A. von Antropoff, O. Hahn, W. and J. Noddack and O. Berg, J. Joly, V. G. Khlopin and M. A. Pasvik, and R. A. Sonder.

H. A. Rowland,[2] C. E. St. John, M. N. Saha, and C. C. Hutchins and E. L. Holden classed uranium with the elements whose presence in the sun is doubtful. J. N. Lockyer attributed to uranium the lines 3931·0, 3943·0, and 3965·8 in the solar spectrum, but the measurements of B. Hasselberg made this doubtful. He found that 75 per cent. of the principal uranium lines are absent from the solar
Fig. 1.—The Geographical Distribution of Uranium Ores.

spectrum. Against this, G. Meyer and H. Greulich found that if less than 7 per cent. of uranium be present, the spectrum of uranium is obscured by the spectral lines of the other metals. The relatively large proportion of iron in the sun is sufficient to account for the observations of B. Hasselberg without accepting the inference that uranium is absent from the sun. J. N. Lockyer reported uranium lines in the spectra of the colder stars. This, and the reports of H. von Sieliger and H. Kienle are doubtful. E. Paneth and co-workers found in 17 meteorites an average of $2 \cdot 3 \times 10^{-6}$ grm. per gram.

The geographical distribution of uranium ores is illustrated by Fig. 1.[3] The main localities are as follow :

Europe.—Virtually all the pitchblende of the **British Isles** [4] is obtained from Cornwall—Redruth, Providence, Wheal Gorland, South Basset, Wheal Edwards, and St. Day. A little has been reported in Devon. Uranium minerals occur near Limoges, and at Symphonen, near Autun, in **France.** There is also a small deposit near Vielsalm, in **Belgium,** and one in Bergell.[5] There is a deposit in **Portugal,**[6] east and west of Vizeu. There is a deposit in **Turkey** near Adrianople. Uranium minerals have been found in **Russia** [7]—Lotsmanskaja, near Ekaterinoslav ; Khutor Golowin, near Shitomit ; Wolf

Island, Lake Omega ; Carelia, Arctic Coast—*vide infra*, Asia. The ore also occurs near Moss, Annerod, Elvestad, Huggenäskilen, Skraatrop, and Arendal in **Norway.**[8] Deposits have been reported in **Germany**[9]—Saxon Voigtland, Schwarzwald, Falkenstein, and Steinig, and in the Siebengebirge. In **Saxony**—Freiburg, Dippoldeswalde, Niederschlag, Schneeberg, Johanngeorgenstadt, Breitenbrunn, Gottesburg, Marienberg, Eibenstock, and Neustädtel. In **Bohemia**—Joachimsthal, Pribram, Zinnwald, and Neudeck ; at Wölsenberg, Bavaria ; and at Rezbanya in **Hungary.**

Asia.—There is an occurrence of mendeléeffite, etc., near Sludjanka in Transbaikalia, **Siberia ;**[10] and in **Turkestan,** at Tjaja Mujun, Prialaj Mountains, Ferghaua. Deposits in **India**[11] have been reported in Bengal ; Pichhli and Banekhap in Gaya District, and Rapur Taluq, Nellore district, Madras ; on Abraki Pahar, east of Banekhap, Central India ; and in Ceylon. There is also a deposit in Burma,[12] and autunite occurs at the Beau Site, Caoson, Nguyen-Binh, and Pia Quac, Cuobang ; south of Andijan, Siberia ;[13] and in the islands of **Japan.**[14]

Africa.—There are deposits of uranium minerals at Katanga, **Belgian Congo,**[15] and at Morogoro district, Tanganyika Territory.[16]

Madagascar.[17]—Betafo.

America.[18]—Uranium deposits have been reported in **Canada**—Villeneuve Mica Mines, Ottawa Co., Quebec (pitchblende) ; Hybla, Hastings Co. ; Peterborough Co. (uraconite) ; Mica Lake, Berthier Co., Quebec (samarskite) ; Lake Pieds des Monts, Charleroix Co. (pitchblende) ; Kearney Sound, Toronto ; Pary Sound, and Butt, Georgian Bay, Ontario (pitchblende). Uranium ores have been reported from many parts of the **United States.**[19] There are small deposits in Arizona ; Connecticut—Middletown, Glastonburg, and Branchville ; North Carolina—Mitchell and Alexander Co. ; South Carolina—Marietta ; Colorado— Black Hawke near Central City, Long Park, Jimtown, Placesville, and Quartz Hill, Gilpin Co. ; South Dakota—Bald Mountain District, Black Hills ; Massachusetts—Chesterfield ; Montana—Pola Mesa, north of La Sal ; Nevada—Wabuska ; New Mexico—Tyrone, and White Signal mining district, Grant Co. ; New Hampshire—Acworth ; Texas—Llano Co. ; Utah—Silver Reef, Mammoth Mine in the Tintic District, Moal, East of the San Rafel swell, and 25 miles south-east of Green River ; and Wyoming—Lusk (uranophane). Uranium also occurs in **Venezuela**[20]—Montanas Negras ; in **Peru,**[21] near Quisque ; and in Placer de Guadaloupe, Chihuahua, **Mexico** ; in Minas Geraes, **Brazil** ; and in **Salvador,** Central America.

Australasia.[22]—Uranium deposits occur at Mount Painter, Radium Hill, Olasy, South Australia ; and Wodgina, West Australia.

The world's production of uranium minerals is, in long tons, approximately :

	1919	1920
United Kingdom	—	60
Czechoslovakia	10	75
Portugal	1,358	430
Madagascar	10	5
United States	12,954	31,318

The uranium minerals have been discussed by B. Szilard,[23] C. Baskerville, etc. Many of these have been treated in connection with the rare earths. The following are the more important of them arranged alphabetically :

Ampangabelte, a hydrated uranyl tantalocolumbate with 19·4 per cent. UO_2. **Anneroedite** is a pyrocolumbate of uranium, yttrium, cerium, and calcium ; it has roughly about 16 per cent. UO_2—*vide* columbium. **Autunite** is also called uranite, and lime-uranium mica. In the idealized case, it can be represented by $Ca(UO_2)_2(PO_4)_2.8H_2O$, and approximates 55 to 62 per cent. UO_2. **Becquerelite,** $(Pb,UO_2)O.2H_2O$. **Betafite,** a hydrated uranium columbatotitanate with 27·15 per cent. UO_3. **Biomstrandite** is a uranium columbatotantalate with about 29 per cent. UO_2—*vide* rare earths. **Braggite** is a variety of fergusonite. **Brannerite,** a complex titanate, $2RO.R_2O_3.3RO_2.3UO_3.18TiO_2.4H_2O$, containing rare earths, 10·3 per cent. UO_2, and 33·5 per cent. UO_3. **Bröggerite** is a variety of uraninite, or pitchblende, approximating 76 to 79 per cent. $UO_2.UO_3$. **Carnotite** in the idealized case approximates $K_2O.2UO_3.V_2O_5.3H_2O$, approximating 62 to 65 per cent. UO_3—*vide* vanadium. **Chalcolite**—a synonym of torbernite. **Chinkolobwite,** $12UO_3.5SiO_2.14H_2O$. **Clarkeite,** $(Na_2Ca,Pb)O.3UO_3.3H_2O$. **Cleveite,** a variety of uraninite with about 66 per cent. $UO_2.UO_3$. **Coracite** is a calcium uranyl uranate approximating 59 per cent. UO_3. **Cuproautunite,** $CuO.2UO_3.P_2O_5.10H_2O$, a cupriferous torbernite. **Cuprouranite,** one of the names for uraninite. **Curite,** $PbO.5UO_3.4H_2O$; **Cyrtolite,** altered zircon. **Dewindtite,** $Pb(UO_2)_2.(PO_4)_2.3H_2O$. **Dumontite,** $2PbO.3UO_3.P_2O_5.5H_2O$. **Ebigite**—*vide* uranothallite. **Ellasite,** or pittinite, is a variety of gummite approximating $(Pb,Ca,Ba)U_3SiO_{12}.6H_2O$, and approximates 61 to 67 per cent. UO_3. **Euxenite** is a titanocolumbate of yttrium, erbium, cerium, thorium, and uranium with 4 to 16 per cent. UO_2—*vide* rare earths. **Fergusonite,** including bragite and tyrite, is a metacolumbate tantalate of yttrium and other rare earths, calcium, and uranium ; and it contains 1 to 8 per

cent. UO_2—*vide* rare earths. **Flutherite** is uranothallite. **Fouthmarierite** approximates $PbO.4UO_3.5H_2O$. **Fritzcheite**, $(U,Mn,V)PO_4.H_2O$. **Gilpinite** is a complex sulphate, $(Cu,Fe,Na_2)O.UO_3.SO_3.4H_2O$, the same as phannite. **Gummite**, including pittinite, is a decomposition product of pitchblende with 61 to 75 per cent. UO_3. **Hatchettolite** is a uranium columbatotantalate with up to about 16 per cent. UO_2—*vide* rare earths. **Ianthinite** is $2UO_3.7H_2O$. **Johannite** is a uranium sulphate containing some copper, and approximates 67 per cent. UO_3. **Lambertite** is a form of uranophane. **Kasolite** is $Pb(UO_2)(SiO_4).H_2O$. **Liebigite** is a hydrated calcium uranyl carbonate approximating uranothallite; and to $CaCO_3.(UO_2)CO_3.20H_2O$. It has about 38 per cent. UO_3. **Mackintoshite** is a uranothorium silicate with about 22 per cent. UO_3—*vide* rare earths. **Maitlandite** is $2(Pb,Ca)O.3ThO_2.4UO_2.8SiO_2.23H_2O$. **Medjidite** is a variety of uranochalcite and calcium uranyl sulphate. **Mendeléeffite** is a hydrated titanocolumbate containing 23·5 per cent. U_3O_8, 15 per cent. of CaO, together with some lead, iron, and rare earths. **Nægite** is a silicate approximating 28·27 per cent. U. **Nasturan,** a variety of pitchblende. **Nivenite** is a decomposition product of nasturan with about 67 per cent. U_2O_5; and **nohlite**, a decomposition product of samarskite with about 14 per cent. UO_2. **Parsonite** is $Pb_2(UO_2)(PO_4)_2.H_2O$. **Phosphuranylite** is a uranyl phosphate, $(UO_2)_3(PO_4)_2.6H_2O$, with 71 to 78 per cent. UO_3. **Pilbarite** approximates $PbO.UO_3.ThO_2.2SiO_2.4H_2O$ with about 27·09 per cent. UO_3—*vide* rare earths. **Pitchblende**—also called uraninite, and nasturan—is approximately U_3O_8, with some lead uranate, and contains 75 to 85 per cent. of UO_2. It also contains rare earths, etc. **Pittinite** is a decomposition product of pitchblende. **Polycrase** is a columbatotantalate of ytterium earths with 0·5 to 20 per cent. UO_2—*vide* rare earths. **Priorite** is $UO_2.UO_3$ with about 3·24 per cent. of thoria—*vide* rare earths. **Randite** is a calcium uranyl carbonate with about 32 per cent. UO_2; and **rauvite**, a calcium uranyl vanadate, $CaO.2UO_3.6V_2O_5.20H_2O$—*vide* vanadium. **Renardite** is $PbO.4UO_3.P_2O_5.9H_2O$. **Rogersite** is the same as nohlite. **Rutherfordine** is a carbonate of uranyl, lead, etc., with about 69·5 per cent. U. This is not rutherfordite, a cerium variety of fergusonite—*vide* rare earths. **Samarskite**—and yttrioilmenite—is a complex columbatotantalate of yttrium, uranium, cerium, iron, etc., containing 10 to 15 per cent. UO_3—*vide* rare earths. **Samiresite** is a titanatocolumbate of lead, uranium, etc., with 21·2 per cent. of UO_2. **Schoepite** is $UO_3.2H_2O$. **Schröckingite** is a uranium carbonate with calcium sulphate. **Sklodowskite** approximates $MgO.2UO_3.2SiO_2.7H_2O$. **Soddite** is $12UO_3.5SiO_2.14H_2O$. **Stassite** is $4PbO.8UO_3.3P_2O_5.12H_2O$. **Thorianite** is an oxide of thorium, uranium, zirconium, lead, iron, and rare earths containing 4·1 to 10·4 per cent. U—*vide* thorium. **Thorogummite** is a hydrated uranyl thorium silicate containing about 22 per cent. UO_3—*vide* rare earths, and thorium. **Toddite** is a variety of columbite with some manganese and iron replaced by uranium; it contains about 11 per cent. of U_3O_8. **Torberite,** or torbernite, is also called chalcolite, cuprouranite, and uranium mica. It is a hydrated uranyl copper phosphate with 56 to 62 per cent. UO_3, and approximates $Cu(UO_2)_2(PO_4)_2.8H_2O$. **Trögerite** is a hydrated uranyl arsenate approximating $(UO_2)_3(AsO_4)_2.12H_2O$, and it contains about 64 per cent. UO_3—*vide* arsenates. **Tyrite** is fergusonite. **Tysonite** is a hydrated basic sulphate of uranium, calcium, copper, and iron, containing 60 to 80 per cent. U. **Tyuyamuyunite** is $CaO.2UO_3.V_2O_5.nH_2O$. **Ulrichite** is a plumbiferous trioxide of uranium. **Uraconite** contains uranium sulphate and approximates 66 to 71 per cent. of U_3O_8. **Uraninite,** and **uranotemnite** are the same as pitchblende—**uranite**—*vide* uranite. **Uranium ochre** is uraconite. **Uranmolybdate** is a uranium trimolybdate. **Uranochalcite,** or uranium green, is a hydrated calcium uranyl sulphate with 30 to 36 per cent. of U_3O_8. **Uranocircite** is a barium uranyl phosphate, $Ba(UO_2)_2(PO_4)_2.8H_2O$, with about 47 per cent. U. **Uranophane** is related to uranotile and approximates $CaO.2UO_3.2SiO_2.6H_2O$, having 53 to 67 per cent. UO_3. **Uranopilite** is a calcium uranyl sulphate with about 77 per cent. UO_3. **Uranopitchblende**—*vide* pitchblende. **Uranosphærite** is a hydrated bismuth uranate, $(BiO)_2U_2O_7.3H_2O$, with about 50 per cent. UO_3. **Uranospinite** is a calcium uranyl arsenate, $Ca(UO_2)_2(AsO_4)_2.8H_2O$, with about 49 per cent. U—*vide* arsenates. **Uranothallite,** also called flutherite, is a hydrated calcium uranyl carbonate, $2CaCO_3.U(CO_3)_2.10H_2O$, approximating 31 to 32 per cent. U. **Uranothorite,** thorite with a high proportion of uranium. **Uranotile** is a hydrated calcium uranyl silicate with about 66·75 per cent. UO_3. **Vietinghofite,** a ferruginous derivative of samarskite with about 9 per cent. UO_3. **Voglianite** resembles zippeite, with 12 per cent. U_3O_8. **Voglite** is a copper uranium carbonate, $(UO_2)Cu(CO_3)_2.10H_2O$, with about 35 per cent. U. **Walpurgite** is a basic bismuth uranyl arsenate, $(UO_2)_3Bi_{10}(OH)_{24}(AsO_4)_6$, with about 16·5 per cent. U—*vide* arsenates. **Yttroersite** is a titanate of yttrium, thorium, and uranium with about 2·22 per cent. U—*vide* rare earths. **Yttrogummite** is the end-product of the decomposition of cleveite, and has about 20 per cent. UO_3—*vide* rare earths. **Yttrotantalite** is a columbatotantalate of yttrium, cerium, etc., with 1 to 5 per cent. UO_3—*vide* columbium. **Zeunerite** is a copper uranyl arsenate, $Cu(UO_2)_2(AsO_4)_2.8H_2O$, with about 56 per cent. UO_3—*vide* arsenates **Zippeite** is a basic uranyl sulphate with 13 to 17 per cent. U_3O_8—*vide* voglianite. **Zirkelite** contains about 1·3 per cent. uranium.

Many other minerals have uranium as an accessory constituent. K. A. Hofmann and F. Zerban [24] reported 0·31 per cent. U_3O_8 in *œschynite*; E. Rimann, in *boden-*

benderite; G. P. Tschernik, 0·03 per cent. U in *cerite*; M. E. Pennington, and B. Szilard, 0·48 per cent., and H. V. Ellsworth, 11 per cent. U_3O_8 in *columbite*. D. Mawson described *davidite*—named after T. W. E. David—as a titanium-iron mineral carrying rare earths and uranium. From the imperfect description it might be a variety of ilmenite. F. Zambonini found 9·87 per cent. UO_2 in *delorenzite*; H. Lange, 2·03 per cent. UO_2 in a red Greenland *fluorspar*; F. Katzer, 5 per cent. UO_2, and B. Szilard, 0 to 4 per cent. U in *hjelmite*; F. Katzer, 0·43 per cent. UO_3 in *kochelite*; B. Szilard, 1·3 to 1·6 per cent. U in *microlite*; K. A. Hofmann and F. Zerban, 0·9 per cent. U_3O_8 in *monazite*; F. Katzer, 1 to 10 per cent. UO_3, and K. A. Hofmann and F. Zerban, 1 per cent. U_3O_8 in *orangite*; G. P. Tschernik, traces of uranium in *orthite*; O. Hauser, 0·1 per cent. U, and B. Szilard, 0·9 per cent. U in *risorite*; B. Szilard, 0·3 to 0·5 per cent. U in *rowlandite*; J. W. Mallet, F. Katzer, and B. Szilard, up to about 3·26 per cent. U in *sipylite*; F. Katzer, and B. Szilard, 1 to 10 per cent. UO_3 in *thorite*; F. Katzer, and B. Szilard, about 4 per cent. UO_3, and K. A. Hofmann and F. Zerban, 0·5 to 3·5 per cent. U_3O_8 in *xenotime*; B. Szilard, up to 10 per cent. U in *yttrialite*; W. E. Hidden and C. H. Warren found a small proportion of uranium in *yttrocrasite*, a titanate of yttrium, thorium, and uranium; H. V. Ellsworth, and T. L. Walker and A. L. Parsons, in *ellsworthite*; H. V. Ellsworth, *lyndochite*; H. V. Ellsworth, *thucholite*; D. Guimaraes, *eschewegite*; and F. P. Venable observed a little uranium in *zircon*; B. Jezek, and A. Krejci, in *pisekite*; and K. Kimura, in *hagatalite*. Traces of uranium—and up to 2 to 3 per cent.—have been reported in the *kolm*, a variety of bituminous coal, of Sweden. C. Winkler[25] found that kolm contains 0·06 to 7 per cent. U_3O_8. G. Nordenskjöld observed that the ash from a bed of carbonaceous sedimentary rock contained 2 to 3 per cent. of U_3O_8. F. Katzer also reported examples of coal-ash containing 2 to 3 per cent. of U_3O_8; and an anthrasitic carbon inclusion in pegmatite with 35·43 per cent. Carnotite and vanadium minerals in Utah are associated with the carbonaceous plant residues in the sandstones. A. P. Forjas, and H. de Carvalho reported uranium in the mineral waters of Corredoura, and Caria, Portugal.

§ 3. The Extraction of Uranium from its Ores

The chief sources of uranium are pitchblende, also called uraninite, and carnotite. The early workers, J. A. Arfvedson,[1] and G. C. Wittstein, following M. H. Klaproth, extracted uranium by digesting powdered pitchblende with nitric acid, or aqua regia, evaporating the soln. to dryness; extracted the soluble matter with hydrochloric acid; precipitated arsenic, lead, etc., with hydrogen sulphide; treated the filtrate with nitric acid and then with ammonium carbonate; boiled the soln. and digested the precipitated uranium, zinc, and cobalt oxides with cold dil. hydrochloric acid, which leaves the uranium oxide as an insoluble residue. J. Persoz boiled the nitric acid soln. with copper oxide or lead oxide and dissolved the precipitated uranium and iron oxides in dil. nitric acid; the soln. was boiled with mercuric oxide, and the copper and mercury precipitated by hydrogen sulphide: the uranium salt alone remains in soln. J. J. Ebelmen, and E. M. Péligot roasted the ore, and washed it with hydrochloric acid before digesting it with nitric acid. L. R. Lecanu and M. Serbat opened the ore by fusion with nitre; and A. Werner by fusion with sodium hydrosulphate, or with hot sulphuric acid. Modifications were used by F. Wöhler, H. Hermann, I. Wertheim, A. Laugier, G. A. Quesneville, J. B. Richter, W. T. Brande, and C. F. Bucholz. These processes are only of historical interest.

At the present time the main purpose in treating uranium ores is the extraction of radium, and uranium salts are produced as a by-product. Starting with pitchblende, a complex ore containing variable proportions of uranium—say 65 to 85 per cent. UO_3—and also compounds of copper, silver, zinc, thallium, rare earths, lead, arsenic, antimony, bismuth, vanadium, columbium, tantalum, molybdenum, tungsten, manganese, iron, cobalt, nickel, alumina, magnesia, lime, silica, sulphur, and selenium—the ore is first concentrated, and then roasted in a reverberatory furnace, to remove sulphur, arsenic, and other volatile impurities. Sodium carbonate or sulphate, or a mixture of sodium carbonate and nitrate, is added to the roasted ore and the mixture fused in the reverberatory furnace. This converts uranium into sodium uranate, and sodium vanadate, molybdate, tungstate, and arsenate are formed. These salts pass into soln. when the cold product is extracted with hot water. The residue is the starting point for the extraction of radium. It can be digested with dil. sulphuric acid, which takes up any uranium as uranyl sulphate. The excess of acid is removed by evaporation, and the residue extracted with water. The residue consists of silica, lead sulphate, and basic bismuth sulphate and arsenate. The two extracts are treated with an excess of sodium carbonate to precipitate the basic carbonates of iron, aluminium, nickel, and cobalt, while the uranium remains in soln. as sodium uranyl carbonate. The liquid is boiled. The clear liquid can then be neutralized with dil. sulphuric acid, boiled, and evaporated, when sodium diuranate, $Na_2U_2O_7.6H_2O$, separates as a heavy yellow precipitate. If ammonium carbonate be employed in place of sodium carbonate, or if the soln. of sodium uranyl carbonate is boiled with ammonium sulphate, ammonium diuranate is produced. If uranium oxide, U_3O_8, is desired, the ammonium salt is calcined. The above procedure, more or less modified, was described by A. Patera,[2] C. Giseke, E. Vysoky, L. Kessler, C. Mann, F. Pisani, R. Arendt and W. Knop, A. T. Elliott, E. F. Anthon, and K. A. Hofmann and E. Strauss. A. L. D. d'Adrian removed the iron as volatile chloride before separating the other metals; R. E. Pearson and E. N. Craig described an electrolytic process.

In order to obtain uranyl nitrate, the oxide is dissolved in nitric acid and the soln. crystallized, or the roasted ore may be dissolved in nitric acid and the soln. evaporated to dryness. The residue is digested with water, and the filtered soln. allowed to crystallize, as in the processes of E. M. Péligot, and J. J. Ebelmen. H. N. McCoy and G. C. Ashman, and E. Wilke-Dörfurt purified the uranyl nitrate by recrystallization from water; and H. C. Bolton also found that in order to get rid of vanadium it is necessary to recrystallize uranyl nitrate from water. F. Giolitti and G. Tavanti allude to the difficulty in removing alkalies from uranyl nitrate, and they succeeded in purifying the salt by dissolving the oxide in nitric acid, converting the soln. into one of ammonium uranate, precipitating by the addition of ammonia, calcining the product, etc.

The uranium can be extracted from carnotite by fusing the powdered mineral with potassium hydrosulphate, and extracting the cold product with water, as recommended by G. Gin, J. H. Haynes, H. Schlundt, R. W. Stimson, and R. B. Moore and K. L. Kithil. The soln. on crystallization furnishes the double sulphates of vanadium and uranium; these are reduced by zinc and sulphuric acid, and the vanadium precipitated from the soln. by the addition of ammonia and ammonium carbonate. When the soln. is boiled, ammonium diuranate is precipitated. In K. B. Thews's process, the ore containing vanadium, uranium, and radium or any of these metals is ground and mixed with two or three times its weight of water. The mixture is heated until the water boils and a reducing agent, such as hydrogen, and an acid solvent, such as an organic acid, e.g. oxalic acid, or a mineral acid, e.g. hydrochloric acid, are added. The soln. is removed from the gangue and worked up for the metals in any suitable way. In place of hydrogen other reducing agents, such as carbon monoxide or formaldehyde, may be used, or if excess of hydrochloric acid be used, a metal such as zinc may be added and the hydrogen generated *in situ*. For the processes of K. B. Thews and F. J. Heinle, and C. L. Parsons and co-workers, *vide* the extraction of vanadium. P. Misciattelli examined the separation of uranium and thorium by the ether extraction of soln. of the mixed nitrates.

The phosphatic uranium minerals are not usually treated for uranium. In the recovery of uranium from laboratory residues, when it is worth while, analogous processes can be used to those which have been suggested for the extraction of uranium from phosphatic minerals. W. Jani [3] boiled the soln. in sulphuric acid, mixed with a little nitric acid, with sodium hydroxide; suspended the washed precipitate in a soln. of sodium carbonate; and saturated the soln. with carbon dioxide. The uranium passes into soln., from which it can be recovered in the usual way. F. Strohmer fused for half an hour a mixture of the phosphate with four times its weight of sodium and potassium carbonates along with some powdered carbon. After treating with hot water and washing until free from soda, the residue is dissolved in hydrochloric acid containing a little nitric acid; and the iron and uranium are precipitated by ammonia, and separated by ammonium carbonate. An analogous process was used by G. Werther, and by C. F. Mohr. W. Knop recommended adding to the hydrochloric acid soln. of the phosphate a mixture of potassium ferrocyanide and glue, and decomposing the precipitated uranium ferrocyanide with sodium hydroxide; W. Heintz treated the nitric acid soln. with tin, so as to precipitate stannic phosphate, etc., leaving uranyl nitrate in soln.; E. Reichardt treated the hydrochloric or nitric acid soln. with ferric chloride, then with an excess of sodium carbonate, and filtered the uranium salt soln. from the ferric phosphate and hydroxide; and G. C. Laube, A. Gawalowsky, and E. Reichardt precipitated the phosphate by means of magnesia mixture.

§ 4. The Isolation of Uranium

As previously indicated, up to the time of E. M. Péligot [1] (1841), observers had mistaken uranium dioxide for the element. They obtained what they considered to be the element by reducing the ordinary oxide with carbon. This serves to show that the carbon reduction process under the conditions which they worked does not proceed far enough. H. Moissan showed that although the uranium oxides are not reduced to the metal by carbon at the highest temp. obtainable with ordinary combustion furnaces, the metal is readily obtained by the carbon reduction process in the electric furnace. H. C. Greenwood found that complete reduction occurs only when the temp. exceeds 1500°.

According to H. Moissan, if a mixture of 500 grms. of uranium tritaoctoxide and 40 grms. of sugar charcoal is rammed into a carbon crucible, the whole is reduced in about 12 minutes in the electric carbon tube furnace ; and on cooling, a metallic ingot, weighing 350 grms., and possessing a bright fracture, is obtained. The metal contains very little carbon ; but if the heating be too long, the metal takes up carbon readily, yielding a highly carburized metal, and ultimately the

U_2C_3-carbide. To prevent the action of nitrogen on the metal it is best to work with the carbon tube of the electric furnace closed at one end. H. Moissan added that uranium containing 0·1 to 0·5 per cent. of carbon may be superficially refined by heating the fragments in a brasque of green uranium oxide for several hours in a forge furnace. To ensure success the crucible containing the uranium oxide and metal must be placed inside a second crucible containing a finely powdered titaniferous brasque, otherwise the metal produced is yellow, and is covered with nitride. J. Aloy also obtained the metal by a similar process. H. Lohmann said that carbon may be removed by heating the metal to a temp. near to its m.p. in vacuo or in a current of neutral gas. Carbon is vaporized without any oxidizing or reducing agents being present.

J. Aloy found that the oxide is reduced by powdered aluminium in the thermite process. The reaction is very vigorous. He said that it is better to use UO_2 than U_3O_8, and he obtained a product with 96–97 per cent. U. A. Stavenhagen and E. Schuchard used 30 grms. of a mixture of a mol of UO_3 with 2 mols of aluminium and 20 c.c. of liquid air. The reaction goes smoothly and brilliantly—J. Aloy added that the product contained a relatively high proportion of aluminium. According to F. Giolitti and G. Tavanti, when a mixture of this oxide with excess of powdered aluminium is thrown on to the surface of fused aluminium maintained at a vivid red-heat, not alloys of aluminium and uranium, mixed with alumina, as stated by H. Moissan, but a mixture of uranous oxide, alumina, and aluminium is obtained. When, however, a mixture of ferric oxide with 10 per cent. of the oxide U_3O_8 is intimately mixed with more than sufficient aluminium filings to reduce both the oxides, and the reaction started by means of barium dioxide and aluminium, the oxide of uranium is reduced to metallic uranium. J. W. Marden and H. C. Rentschler, and J. Aloy also reduced the oxide by heating it with magnesium ; and E. K. Rideal obtained uranium of 98 to 99 per cent. purity by heating in an atm. of hydrogen, in a magnesia-tube, in an electric furnace, a mixture of 80 per cent. of uranium oxide and 20 per cent. of magnesium powder compressed into rods. The finely-divided " uranium black " was pyrophoric, and the hydrogen was displaced by carbon dioxide in the apparatus before the product was exposed to air. The excess of magnesium was removed by washing with dil. acetic acid. If the oxide be reduced by a mixture of sodium and magnesium in the presence of calcium chloride in a steel cylinder at a bright red-heat, E. K. Rideal obtained a greyish-black powder containing 99·4 to 99·6 per cent. of uranium with traces of iron. A. Burger, H. Kuzel and E. Wedekind, and A. S. Cachemaille found that uranium trioxide is reduced by the vapour of calcium in vacuo ; and W. Jander, and J. W. Marden obtained uranium by heating uranium oxide with metallic calcium in a welded iron crucible embedded in charcoal for 40 minutes at 950°–1250°. The resulting mass is then treated with ammonium chloride soln. to remove the unchanged calcium, and the residual powder is levigated, when a light black powder is separated which consists of highly oxidized uranium. The remaining powder contains particles of iron, which can be separated by a magnet, and the residue is then passed through a sieve, which retains coarse, impure powder and gives a fine black powder containing about 97·2 per cent. U, 2·5 per cent. Fe, and 0·3 per cent. O, the yield being about 66 per cent. of the theoretical. If the crucible is prepared with a thick lining of lime, a product is obtained containing 99·9 per cent. U, and not more than 0·09 per cent. O, but the yield is only 27 per cent. of the theoretical. J. F. Goggin and co-workers found that the yield in the reduction of the oxide by calcium is small. The Electric Furnaces and Smelters, Ltd., reduced the oxide by heating it in admixture with calcium carbide and a silicide—e.g. ferrosilicon.

E. M. Péligot reduced uranium tetrachloride admixed with potassium chloride and sodium, and covered with potassium chloride, in a porcelain crucible, contained in a graphite crucible, packed with dry powdered carbon, and the temp. rapidly raised to redness. The cold product was lixiviated with water, and there

remained a grey powder with a few metallic globules.   E. M. Péligot first reduced the tetrachloride with potassium in a platinum crucible, and found that the uranium was contaminated with platinum.   J. L. C. Zimmermann also reduced the tetrachloride with sodium.   D. Lely and L. Hamburger heated the tetrachloride with sodium in an exhausted steel vessel, and rendered the metal compact by heating it in an alundum tube in an exhausted vessel.   W. I. Baragiola used a similar process.   R. W. Moore distilled the tetrachloride in a current of chlorine, and the sodium in vacuo, and cut it in pieces under dry benzene.   The mixture was heated in a steel bomb in vacuo, and the product extracted first with absolute alcohol to remove excess of sodium, then with water to remove sodium chloride, and finally with 2 per cent. acetic acid.   The heavy brownish residue of metallic uranium was washed with acetone and dried in vacuo.   A yield of 90 per cent. of the theoretical quantity of metal containing 99·8 per cent. uranium was readily obtained.   The powder was very pyrophoric, but it can be pressed into discs in a hydraulic press in an atm. of nitrogen, when it is no longer pyrophoric.   These discs may be melted by the arc in an atm. of rarefied argon to bright, steel-grey, ductile, metallic buttons which readily tarnish on exposure to the air.   J. W. Marden also reduced the chloride by sodium with calcium chloride as a flux in a closed vessel.   A. Roderburg added that when the uranium chloride is reduced by sodium in a porcelain vessel, the uranium is contaminated with aluminium and silicon ; and when in iron vessels, with iron.   Nickel, magnesia, graphite, or silver vessels are rapidly destroyed ;   and nickel-steel is more resistant than other steels. M. A. Hunter and A. Jones obtained 99 per cent. uranium by reducing the anhydrous chloride with sodium in a steel-bomb.   J. W. Marden reduced the uranium halide or potassium uranium fluoride by means of calcium in the presence of calcium chloride ;   pressed the powdered metal into a desired shape and heated it until it was homogeneous and ductile.   J. W. Marden and H. C. Rentschler observed that uranium readily alloys with metals, and interacts with lime and magnesia refractories, but thoria crucibles give good results.   J. F. Goggin and co-workers found that a good yield of very pure fused uranium is obtained by the reduction of uranium chloride with a 10 per cent. excess of metallic calcium ; the operation is carried out in an alundum crucible placed inside a nichrome-wound reduction bomb which is placed inside a steel cylinder from which the air is exhausted.   The product obtained by this method was a hard, brittle metal containing 0·57 per cent. Fe, 0·09 per cent. C, and 0·03 per cent. O when commercial calcium was used, but a much purer product, containing only 0·01 per cent. Fe, was obtained by the use of resublimed calcium.   The ingot showed fine crystalline markings, had a silvery lustre and convex surface, and appeared to be sound.   E. M. Péligot stated that the tetrachloride is reduced to the metal by aluminium, but H. Hermann found that the vapour of the tetrachloride is not reduced to uranium by that metal. E. Botolfsen reduced the oxide with calcium in vacuo, and removed the calcium and calcium oxide by 2 per cent. acetic acid.   J. W. Marden reduced uranium ammonium chloride with aluminium.   H. Moissan preferred to reduce sodium uranium hexachloride, Na_2UCl_6.   300 grms. of the double chloride and 100 grms. of freshly-cut sodium were introduced in alternate layers into a strong iron cylinder, which was closed with a screw stopper.   The cylinder was heated for 25 minutes over a brightly-burning wood fire.   The heat of the reaction raised the vessel to a white-heat in a few minutes.   After cooling, the cylinder was opened, and the powdery contents first treated with alcohol at 96° in order to remove the excess of sodium, then washed quickly with cold, previously boiled water, and finally with alcohol and ether.   This process was also employed by W. G. Mixter.   J. Aloy similarly reduced the lithium or potassium salt with alkali metal.

    H. Hermann found that the potassium salt is not reduced to uranium by zinc in the presence of sodium chloride.   According to A. Commaille, magnesium deposits the hydrated uranic oxide from aq. soln. of uranium oxalate ; S. Kern obtained a

similar result with the nitrate in aq. soln.; and G. Gore obtained no reduction by adding silicon to the molten fluoride.

L. Schicht found that the electrolysis of acetic soln. of uranium salts reduces the uranic to uranous salts, and from neutral soln. a little uranium (possibly the oxide) is formed; a similar result was obtained with alkaline soln. containing acetic, citric, or tartaric acid, or sugar. G. Gore obtained no uranium by the electrolysis of an aq. soln. of the fluoride, nor by the electrolysis of the molten fluoride. C. Luckow obtained a little uranium by the electrolysis of a neutral salt soln. E. F. Smith obtained only the uranosic oxide by the electrolysis of aq. soln. of the acetate, formate, and nitrate.

H. Moissan observed that fused sodium uranium hexachloride can be easily electrolyzed, and spongy uranium, often containing small crystals, is deposited at the cathode. A potential difference of 8 to 10 volts and a current of 50 amps. was employed. The bath is kept liquid by the heating action of the current itself. The double chloride was contained in a cylindrical porcelain vessel, and electrodes of carbon were used. The vessel was closed by a ground porcelain plate, carrying the two electrodes and a glass tube through which was passed, above the fused chloride, a current of hydrogen free from nitrogen. When quite cold the contents of the vessel were quickly treated with ice-cold water, and washed with alcohol—finely divided uranium decomposes water at ordinary temp. With iron electrodes, silver white, fine-grained alloys of iron and uranium are produced. These alloys can be filed with ease. R. E. Pearson and E. N. Craig passed a current through a sulphuric acid cell with pasty uranium oxide in the cathode chamber, and obtained uranium. J. Aloy also found that during the electrolysis, the uranium alloys with iron, aluminium, cadmium, and platinum electrodes. F. H. Driggs and W. C. Lilliendahl obtained the metal by the electrolysis of potassium uranous fluoride in a molten mixture of sodium and calcium chlorides, using a carbon crucible as anode and a molybdenum wire as cathode. The Wolframlampen A.G. found that soln. of salts in conducting organic solvents—e.g. acetone —which exert no oxidizing action, give, on electrolysis, deposits of uranium on nickel, platinum, etc. J. Ferée electrolyzed an aq. soln. of uranous chloride using a mercury cathode, and obtained uranium amalgam. When this is distilled in vacuo, it furnishes *pyrophoric uranium*. R. M. Keeney obtained alloys with aluminium and iron electrolytically and found that iron alloys with over 20 per cent. of uranium were pyrophoric, and more markedly so with higher proportions of uranium.

The process of H. Kuzel[2] for obtaining colloidal chromium, molybdenum, and tungsten (*q.v.*) has not been followed closely for **colloidal uranium**. T. Svedberg prepared the **isobutylalcosol** by the electric dispersion method—**3**. 23, 10. H. Agulhon and T. Robert also prepared colloidal uranium by the electrical dispersion process.

§ 5. The Physical Properties of Uranium

D. I. Mendeléeff [1] discussed some analogies in the **colour** of chromium, molybdenum, tungsten, and uranium. E. M. Péligot described the uranium which he prepared as a grey powder ; and H. Moissan observed that the powder is liable to form a nitride which produces a yellow film on the metal. E. K. Rideal described the metal which he prepared as a greyish-black powder. H. Moissan found that when prepared by the carbon reduction process uranium furnishes an ingot with a bright fracture. When the metal is of a high degree of purity it is white, with a fainter bluish tinge than iron, and can be polished like iron. If the metal has a yellow tinge, some nitride is present. R. W. Moore said that by fusing the metal in vacuo, it can be cast into small ingots and then has the appearance of polished iron. J. F. Goggin and co-workers found that the ingot of uranium shows fine crystalline markings and has a silvery lustre ; H. Moissan stated that when prepared by electrolysis fairly large, well-defined crystals may be formed on the cathode. J. C. McLennan and R. W. McKay found that the **X-radiograms** of uranium indicated a body-centred, cubic lattice with $a=3.43$ A.

E. M. Péligot gave 18·33 to 18·40 for the **specific gravity** of the metal ; J. L. C. Zimmermann, 18·485 at 13°/4° in vacuo. J. Aloy said that a sample obtained by the aluminothermic process had a sp. gr. 16·5—the sample was presumably contaminated with aluminium. J. C. McLennan and R. W. McKay obtained 19·6 for the density from the X-radiograms. J. L. C. Zimmermann calculated the **atomic volume** to be 12·84. E. Donath and J. Mayrhofer made some observations on this subject. C. del Fresno discussed the at. vol., and W. Biltz and K. Meisel estimated it to be 12·6 at absolute zero. E. J. Cuy estimated the **atomic radius** of U···· to be 1·22 A. ; H. G. Grimm, V. M. Goldschmidt, L. Pauling, E. Herlinger, and E. T. Wherry also studied the at. radius of uranium, from which it follows that the value for quadrivalent uranium atoms is 0·97 to 1·05 A. P. Vinassa studied the mol. number. H. Moissan observed that uranium is easily filed ; it does not mark glass ; and when it has taken up a little carbon from the crucible, it can be tempered. R. W. Moore found that the metal is very **ductile ;** some buttons of the metal were rolled cold from a thickness of 5 mm. to small sheets about 0·375 mm. thick. D. Lely and L. Hamburger found uranium to be less malleable than thorium. P. W. Bridgman found the **compressibility** of uranium at 30° to be $\delta v/v_0 = -10^{-7}(9.66 - 2.5 \times 10^{-5}p)p$, and at 75°, $\delta v/v_0 = -10^{-7}(9.55 - 2.2 \times 10^{-5}p)p$, where p denotes the press. in kgrms. per sq. cm. for **values** of p between 1 and 12,000. The compressibility, β, at 30° is 0.0_6966 ;

and $\delta\beta/\beta\delta p=0\cdot0_552$. L. H. Adams found that $\delta\beta=-0\cdot05$. J. Laissus discussed the **diffusion** of uranium in iron.

E. Donath gave $0\cdot0249$ for the **specific heat** at $0°$; and J. L. C. Zimmermann, $0\cdot0276$ at $0°$. A. Blümcke found $0\cdot0280$ for the sp. ht. between $0°$ and $98°$, and $6\cdot66$ for the atomic heat; whilst J. Dewar gave $0\cdot0138$ for the sp. ht. at $-223°$, and $3\cdot29$ for the at. ht. H. Fritz made some observations on the relation of the sp. ht. to some of the other properties of the metal. H. Moissan found that uranium melts less easily than platinum, chromium, and molybdenum, but more easily than tungsten and vanadium. J. Maydel discussed some relations of the sp. ht. W. Guertler and M. von Pirani gave $1850°$ for the **melting point**; A. Fischer and E. K. Rideal found that a specimen with $0\cdot4$ per cent. of carbon melted in vacuo between $1300°$ and $1400°$. W. R. Mott gave $1600°$ for the m.p. According to H. Moissan, uranium may be distilled in an electric furnace and the vapour furnishes small metallic spheres free from carbon. E. Botolfsen observed that uranium does not sublime in a high vacuum below its m.p. According to H. Moissan, the **boiling point** of uranium is above that of iron. W. R. Mott estimated the b.p. to be $3500°$. W. G. Mixter gave $303\cdot9$ Cals. for the **heat of oxidation** to UO_3; and for the heat of oxidation to U_3O_8, $\frac{1}{3}$ of $895\cdot5$ Cals. per gram-atom. E. D. Eastman calculated $10\cdot5$ for the **entropy** of uranium; G. N. Lewis and co-workers gave $11\cdot1$; W. Herz, $15\cdot37$; and B. Bruzs, $24\cdot1$ at the m.p. $2100°$ K. R. D. Kleeman discussed the internal and free energies of uranium; and W. Herz, the entropy.

V. Henri,[2] and J. C. Ghosh and B. N. Mitter found that the **extinction coefficients** of mixtures of uranyl salts and organic acids are greater than the sum of the extinction coeff. taken separately; and this was cited as evidence of the formation of unstable intermediate compounds. A. Müller discussed the colour. A. Dorabialska studied the radiant energy.

Uranium salts do not show a **flame spectrum,** nor yet a simple spark spectrum; and W. Huggins [3] found that uranium oxide in the oxyhydrogen flame shows only the continuous spectrum characteristic of red-hot solids. The **spark spectrum** is produced if a condenser is in the circuit. R. Thalén first made a drawing of the spark spectrum, and later gave some measurements of the spectral lines. The spectral lines are exceptionally numerous, but as shown by E. Formanek, and A. S. Russell and R. Rossi, none is distinctive enough to serve for the detection of small quantities of uranium spectroscopically. The more important lines in the spark spectrum are 5528, 5494, 5482, 5480, 5478, and 5475 in the green, and 4473, 4362, and 4341 in the indigo-blue. The spark spectrum was examined in more detail by J. N. Lockyer, E. Demarçay, G. Meyer and H. Greulich, O. Lohse, F. Exner and E. Haschek, A. Hagenbach and H. Konen, J. H. Pollok, C. E. Gissing, and J. M. Eder and E. Valenta. G. Meyer and H. Greulich found that the spectral lines are masked by those of other metals unless the uranium is present in considerable concentration—say 7 per cent. C. Porlezza and A. Donati discussed the electroscopic detection of uranium. E. J. Allin examined the underwater spark spectrum. H. Nagaoka and T. Futagami examined the spectral lines due to the transformation products of uranium. The **arc spectrum** was examined by J. N. Lockyer, F. Exner and E. Haschek, C. C. Kiess and W. F. Meggers, K. W. Meissner, J. M. Eder and E. Valenta, E. Z. Stowell, and B. Hasselberg; the **ultra-violet spectrum,** by R. J. Lang, H. Nagaoka and T. Futagami, F. Exner and E. Haschek, and O. Lohse; and the **ultra-red spectrum,** by C. C. Kiess and W. F. Meggers. W. W. Coblentz found uranium oxide gives a continuous spectrum in the ultra-red with hazy maxima at $2\cdot8\mu$ and $3\cdot4\mu$. The anomalous *dispersion* was discussed by H. Ebert; and the effect of *pressure* by W. J. Humphreys. The *Stark effect* was studied by H. Nagaoka and Y. Sugiura. No **series spectrum** has been detected; C. C. Kiess and W. F. Meggers, and P. G. Nutting discussed the structure of the lines; and J. C. McLennan and co-workers, the relation between the electronic structure and the spectrum. H. Nagaoka and T. Futagami compared the spectra

of thorium, helium, and uranium. J. C. McLennan and E. Cohen studied the **absorption spectrum** of the vapour of uranium. E. T. Wherry detected uranium in minerals from their absorption spectra.

Numerous researches have been made on the absorption spectrum of soln. of uranium salts. These include observations by J. H. Gladstone,[4] G. G. Stokes, H. C. Sorby, W. Böhlendorff, E. Hagenbach, S. Kato, J. M. Hiebendaal, H. Oeffinger, H. Morton and H. C. Bolton, H. Kayser, etc. All the uranium salts, solid or in soln., show an absorption spectrum. The exact position of the bands is usually dependent on the temp. With a rise of temp. the bands are usually displaced towards the red. Thus, H. Bremer found for one of the bands of uranyl sulphate, 4906 (20°), 4909 (40°), 4915 (60°), and 4992 (80°), and with another band, 4738 (20°), 4741 (40°), 4743 (60°), and 4745 (80°); whilst for one of the bands of uranyl nitrate, 4859 (20°), 4868 (40°), 4870 (60°), and 4872 (80°), and for another band, 4696 (20°), 4702 (40°), 4706 (60°), and 4708 (80°). Similar results were obtained with some double sulphates, and with the acetate. H. Morton and H. C. Bolton made similar observations with respect to the double salts—sulphate, carbonate, and oxalate. J. M. Hiebendaal, on the contrary, observed that temp. had no perceptible influence on the position of the bands. H. C. Jones and J. S. Guy found that the uranyl bands become more diffuse with rise of temp.; and H. C. Jones and W. W. Strong, and M. Cantone studied this subject. For the effect of low temp., *vide infra*, phosphorescence spectra.

H. Morton and H. C. Bolton found that solid *uranyl fluoride* exhibited the bands $\lambda=4930$, 4770, 4661, 4480, 4310, and 4180; the aq. soln., 4780, 4620, 4460, 4330, 4195, and 4055; the soln. in hydrofluoric acid, 4820, 4665, 4480, 4340, and 4200; and *potassium uranyl fluoride*, 4880, 4800 to 4720, 4630 to 4580, and 4490; M. Cantone, and E. L. Nichols and E. Merritt also examined *ammonium uranyl fluoride*. According to H. Morton and H. C. Bolton, solid *uranyl chloride* has absorption bands for $\lambda=4920$, 4750, 4620, 4480, 4340, and 4220; and H. Becquerel studied the pleochroism of the salt. E. Formanek found for the aq. soln., six absorption bands : 4913, 4748, and, with dil. soln., 4572, 4430, 4289, and 4146, as well as a dark one in the violet. E. Deussen gave 4900, 4755, 4580, 4410, 4285, and 4140 with the bands 4025, 3925, 3800, and 3710 in the extreme violet and ultra-violet. Observations were also made by H. Oeffinger, O. Knoblauch, and H. Morton and H. C. Bolton. J. Formanek's results are illustrated by I, Fig. 2. A conc. soln. of uranyl chloride in hydrochloric acid shows only a small band at 4925, but with dilution, the bands 4975, 4630, 4442, 4289, and 4150 appear— II, Fig. 2. According to J. Formanek, when a soln. of a uranyl salt—say the chloride—is reduced by zinc and hydrochloric acid, there are three stages in the process. In the first stage there are eight bands, *viz.* 6500, 6718, 6304, 5497, 4961, 4844, 4566, and 4307—III, Fig. 2; the first and second are also shown by very dil. soln. As reduction proceeds, new bands—6367, 6165, 6030, 5782, 5231, 5065, and 4514—appear, so that the whole spectrum has twelve bands—IV, Fig. 2. As the reduction proceeds further, the liquid becomes dirty green, and the third stage appears with no new bands, but the intensity of single bands is altered— V, Fig. 2 ; 6500 and 6718 are weakened, while 6367, 6165, and 5231 are strengthened. The presence of iron, cobalt, nickel, chromium, aluminium, and zinc does not disturb the phenomena. H. C. Jones and W. W. Strong also studied the effect of reducing agents on a soln. of uranyl salts in different solvents ; and of oxidizing agents—hydrogen dioxide, and nitric acid—on uranous salt soln. E. Deussen also examined the absorption spectra of soln. of uranyl chloride in alcohol, and glycerol ; and H. C. Jones and W. W. Strong examined the absorption spectra of uranyl chloride in methyl, ethyl, propyl, isopropyl, butyl, and isobutyl alcohols, ether, methyl and ethyl esters, formamide, glycerol, acetone, and on aq. soln. in the presence of calcium, zinc, and aluminium chloride. According to A. Müller, the colour of uranyl salts is, in general, yellow, but the presence of hydroxyl or keto-groups, particularly in the a- or ortho-positions, displaces the colour strongly

towards the red.   The benzene nucleus also acts strongly in displacing the colour towards the red end of the spectrum, particularly when the uranyl group is directly connected with phenolic oxygen.   H. L. Howes, and H. Morton and H. C. Bolton examined the absorption spectra of the double salts : *ammonium uranyl chloride*, and *potassium uranyl chloride*, when solid, and in soln. ; and H. L. Howes, *rubidium* and *cæsium uranyl chlorides*.   E. Becquerel also studied soln. of the potassium salt.   H. Becquerel studied the pleochroism of the crystals.   H. C. Jones and W. W. Strong also studied the absorption spectra of soln. of *uranyl bromide*.

E. Deussen found for aq. soln. of *uranyl sulphate* absorption bands for $\lambda=4885$, 4725, 4560, 4410, 4310, 4180, 4060, and 3950.   Observations were also made by W. Böhlendorff, J. W. Hiebendaal, H. Bremer, N. Titlestad, M. Cantone, H. C. Jones and J. S. Guy, H. C. Jones and W. W. Strong, and E. L. Nichols and H. L. Howes, and H. Morton and H. C. Bolton gave for neutral aq. soln. the bands 4955, 4750, 4580, (4475), 4340, 4210, and 4100 ; and for acidic soln., 4890, 4780, (4520), 4370, 4320, 4210, and 4090.   E. Deussen also examined soln. in alcohol, and in glycerol ; and H. C. Jones and W. W. Strong, in conc. sulphuric acid.   J. Moir gave for soln. of uranyl sulphate in sulphuric acid, bands with the centres at 5650, 5410, 5140, and 4920.   H. L. Howes examined the spectra of soln. of this salt.   H. Morton and H. C. Bolton found for aq. soln. of *ammonium diuranyl sulphate* bands at
FIG. 2.—Absorption Spectra of Solutions of Uranium Chloride.

4875, 4720, 4575, (4480), 4330, and 4210 ; *ammonium uranyl sulphate*, at 4935, 4800, 4620, 4450, 4330, 4240, and 4100 ; *sodium uranyl sulphate*, at 4875, 4775, 4580, 4440, 4335, and 4180 ; *potassium uranyl sulphate*, at 4790, 4540, 4370, 4230, 4100 ; and *rubidium uranyl sulphate*, at 4885, 4805, 4645, 4475, 4325, 4205, and 4050. M. Cantone also examined ammonium uranyl sulphate ; E. L. Nichols and E. Merritt, potassium uranyl sulphate ; and E. L. Nichols and H. L. Howes, ammonium, potassium, and rubidium uranyl sulphates, as well as *cæsium uranyl sulphate*. H. Morton and H. C. Bolton also found absorption bands with soln. of *thallous uranyl sulphate* at 4905, 4630, 4480, 4295 ; and with *magnesium uranyl sulphate*, at 4790, 4540, 4370, 4230, and 4100.   These soln. show similar spectra, indicating that the double salts are all decomposed in aq. soln. ; this is supported by the fact that the solid salts also show different spectra.   Solid potassium uranyl sulphate has bands at 4805, 4690, 4520, and 4340.   H. L. Howes also examined the spectra of soln. of this salt at different temp.   H. Morton and H. C. Bolton found for *ammonium uranyl carbonate*, bands at 4630, 4450, 4350, 4240, 4125, and 4030 ; *potassium uranyl carbonate*, at 4655, 4450, 4350, 4235, 4130, and 4035 ; and *sodium uranyl carbonate*, at 4665, 4510, 4355, 4250, 4120, and 4045.   H. Oeffinger also made observations on uranyl carbonate.   H. Becquerel studied the pleochroism of *uranyl nitrate*.   J. Moir gave for the centres of the bands of solid uranyl nitrate $\lambda=5600$, 5350, 5100, and 4850.   H. Morton and H. C. Bolton found for the absorp-

tion bands in aq. soln. 4880, 4720, 4550, 4400, 4280, 4160, and 4040 ; J. Formanek, 4867, 4705, 4545, 4425, 4290, and 4150—I, Fig. 3 ; and E. Deussen, 4860, 4720, 4540, 4380, 4290, 4150, 4020, 3870, 3790, and 3690. Observations were also made by W. Böhlendorff, O. Knoblauch, E. Hagenbach, J. M. Hiebendaal, H. Oeffinger, H. Bremer, J. C. Ghosh and B. N. Mitter, L. J. Boardman, V. R. von Kurelec, G. H. Dieke and A. C. S. van Heel, F. E. E. Germann, H. L. Howes, H. C. Jones and J. S. Guy, M. Cantone, and E. L. Nichols and E. Merritt. According to J. Formanek, the absorption spectrum in soln. of ethyl alcohol has bands at 4830, 4657, 4500, 4350, 4214, and 4085—II, Fig. 3. J. M. Hiebendaal also examined alcoholic soln. ; H. Morton and H. C. Bolton, soln. in alcohol, ether, glycerol, and acetic ether ; E. Deussen, soln. in methyl and ethyl alcohols, acetone, and glycerol ; and H. C. Jones and W. W. Strong, of soln. of uranyl nitrate in methyl, ethyl, and propyl alcohols, acetone, methyl ester, and nitric acid. Observations on *uranyl phosphate* were made by H. C. Sorby, C. Horner, and E. L. Nichols and E. Merritt. H. Morton and H. C. Bolton gave for solid monouranyl phosphate, 4825, 4700, 4580, 4405, and 4290 ; for the aq. soln., 5060, 4775, 4615, 4480, 4345, and 4240 ; for aq. soln. of diuranyl phosphate, 4870, 4720, 4580, 4425, 4280, and 4170 ; and for aq. soln. of *calcium uranyl phosphate*, 4820, 4675, 4520, 4350, 4220, and 4110. H. W. Vogel made some observations on *uranyl hydroxide*; M. Cantone, on *ammonium uranate*; J. Moir found that autunite, or *calcium uranyl phosphate*, has bands with centres at 5750, 5540, 5290, and

FIG. 3.—Absorption Spectra of Solutions of Uranyl Nitrate.

5080 ; *uranyl metaphosphate* in solid metaphosphoric acid, 5900, 5600, 5420, 5150, and 4950 ; and *uranyl sodium metaphosphate* in microcosmic salt lead, 6020, 5620, 5430, and 5170. The crystals of *autunite* and of *torbernite* were examined by F. Rinne. H. Kahler studied the band spectra of crystals containing *uranium oxide*. E. Deussen, H. Morton and H. C. Bolton, W. Böhlendorff, H. Oeffinger, O. Knoblauch, H. C. Jones and J. S. Guy, H. C. Jones and W. W. Strong, V. Henri and M. Landau, M. Cantone, E. H. Harvey, E. L. Nichols and E. Merritt, J. Moir, and H. Bremer studied *uranyl acetate* and its double salts ; H. Morton and H. C. Bolton, *uranyl formate* ; E. Deussen, H. Morton and H. C. Bolton, V. Henri and M. Landau, and W. Böhlendorff, *uranyl oxalate* and its double salts ; H. Oeffinger, *uranyl citrate*, *uranyl tartrate*, and *potassium uranyl cyanide* ; and A. Mazzucchelli and co-workers, a number of organic salts. J. Formanek observed that uranyl salts react with alkanna tincture ; for if a neutral soln. of uranyl chloride or nitrate be added to tincture of alkanna, the liquid becomes green, and there is then a strong absorption band at 6870, and a feeble one at 6315. This is characteristic of uranium.

H. Morton and H. C. Bolton found that solid *uranous fluoride* has absorption bands at 5890, 5530 to 5210, 5020 to 4700, and 4400, and with maxima at 6670, 5455, 5280, 4840, and 4770, whilst *potassium uranous fluoride* has maxima at 6600, 6340, 6140, 5940, 5370, 5240, 4910, and 4760. The absorption spectra of soln. of *uranous chloride* were examined by H. Oeffinger, A. Mazzucchelli and O. G. d'Alceo, and J. L. C. Zimmermann. E. Becquerel found for the solid salt bands at λ=6940*, 6850, 6720, 6550, 6310, 6110*, 5850, 5760, 5650, 5610*, 5570*, and 5485, with broad bands at 5190, 4940, and 4780 ; and with aq. soln., for λ=7056, 6570*, 6530*, 6450, 6310, 6110, 5880, 5540*, 5500*, 4995 (broad), 4960*, and 4740*— where the * indicates strong bands. H. C. Jones and W. W. Strong examined soln. of uranous chloride in methyl ester, in methyl, ethyl, propyl and isopropyl alcohols, acetone, ether, and glycerol ; and in the presence of aluminium chloride and various acids ; and T. R. Merton, soln. in acetone, acetonitrile, ethyl acetoacetate, ethyl alcohol, and acetophenone. H. C. Jones and W. W. Strong also studied the absorption spectrum of *uranous bromide*. H. Oeffinger, A. Mazzucchelli

and O. G. d'Alceo examined the absorption spectra of aq. soln. of *uranous sulphate*, and J. M. Hiebendaal, of alcoholic soln. E. Becquerel found for the solid salt bands at 6900, 6720 ?*, 6650*, 6550, 6450, 6310, 6150, 6100, 5890, 5530*, 5490*, 5400, and 5000; and for aq. soln., at 7056, 6570*, 6530*, 6450, 6310, 5530*, 5490*, and 4980 (broad). H. W. Vogel made observations on *uranous nitrate*; H. Oeffinger, L. C. Beard and O. M. Reiff, and H. C. Jones and W. W. Strong, on *uranous acetate*; and A. Mazzucchelli and co-workers, on a number of organic salts.

The absorption spectrum of the canary-yellow *glass* coloured by uranium was found by E. Hagenbach to furnish bands between 5110 and 4860, 4700 and 4600, and at 4500; H. W. Vogel said that the bands are similar to those with uranyl nitrate, but are displaced a little more towards the red. O. Lubarsch observed, with thin layers, bands between 5070 and 4840, and 4710 and 4620, and with thick layers, bands between 6520 and 6460, 6230 and 6150, and 5930 and 5870; these he referred to uranous oxide. The absorption spectrum of uranium glass was studied by J. B. Burke, C. Camichel, R. A. Houstoun, J. Becquerel, M. Luckiesh, E. L. Nichols and E. Merritt, T. Dreisch, R. C. Gibbs, E. Graviola and P. Pringsheim, F. G. Wick, W. T. Anderson and L. F. Bird, etc.

Uranyl salts in soln. exhibit a greenish fluorescence. E. Becquerel [5] found the **fluorescence** or **phosphorescence spectrum** of uranyl chloride to have bands of wave-lengths 6230, 5955, 5685, 5433, 5176, and 4980; uranyl sulphate, 6620, 6262, 5955, 5690, 5418, 5170, and 4945; uranyl nitrate, 6544, 6180, 5810, 5860, 5590, 5325, 5090, and 4920; and uranyl acetate, 6525, 6180, 5860, 5590, 5325, 5090, and 4920. The bands for the nitrate and acetate occupy nearly the same parts of the spectrum, but with the chloride and sulphate the bands are near the red end. According to E. L. Nichols and H. L. Howes, the phosphorescence spectrum of uranyl sulphate, $UO_2SO_4.3H_2O$, consists of eight equidistant bands, the first and eighth of which disappear at the temp. of liquid air. The remaining bands are resolved into groups of narrow line-like bands, the homologous members of which form series having constant frequency intervals, ranging from 85·7 in cæsium uranyl sulphate to 83·0 in potassium uranyl sulphate. The fluorescence groups are distinguished by a strong pair of bands about eight frequency units apart and several weak bands some of which are doublets. There is a shift of all bands towards the violet, with increasing mol. wts., of about fifteen frequency units in passing from the spectrum of uranyl sulphate to that of cæsium uranyl sulphate.

G. G. Stokes noticed that the phosphorescence spectrum and the absorption spectrum of uranyl salts slightly overlapped. H. Morton and H. C. Bolton also noted coincidences in the positions of several fluorescence and absorption bands of the uranyl salts; and H. and J. Becquerel and H. K. Onnes also noted coincidences in the narrowed bands at low temp. E. L. Nichols and E. Merritt found that in the case of potassium uranyl sulphate, the bands 4760 and 4920 of the absorption spectrum coincide with those of the phosphorescence spectrum; and they are reversible, in that the bands may appear as absorption or luminescence bands according to the conditions under which they are observed. This reversibility was first described by H. Becquerel in 1885 with soln. of uranyl nitrate. H. L. Howes also mentioned the reversibility of the 5080 and 4880 bands of the double uranyl chlorides. When uranyl salts are crystallized in violet light, they exhibit a green luminosity of sufficient persistence to be observed in a phosphoroscope, but the same phenomenon cannot be detected thus in soln. of these salts. J. Perrin said that fluorescence and phosphorescence are not to be distinguished by the greater or lesser persistence of emission, but by the action of a change of temp. and of infra-red radiation; and that the luminosity of uranyl salts should be regarded as a true fluorescence. Of soln. of uranyl salts, that of the sulphate in water containing an excess of sulphuric acid shows the greatest fluorescence. The fluorescence of the sulphate is considerably greater in sulphuric acid soln., being only one-fourth or one-fifth that of the solid salt. The average life of the luminosity is about 5×10^{-4} sec. The luminosity is

regarded as a "prolonged fluorescence" analogous to the brief fluorescence of dyes such as fluorescein, the persistence of luminosity of which is of a much smaller magnitude. Fluorescence of the uranyl salts is considerably reduced by the addition of various substances such as halide salts, organic acids, etc. Mere traces of hydrochloric acid or of alcohol greatly diminish the fluorescence of the sulphate when dissolved in sulphuric acid. J. Perrin observed that the presence of eosin lowers the fluorescence of uranium ; and M. Privault, that quinol inhibits the photochemical oxidation and the fluorescence of uranium. R. Coustal found the permanent luminescence of crystalline solids to be independent of time, temp., and previous insolation ; that ultra-red radiations are without effect ; but it is most intense when the ultra-violet fluorescence is greatest. The permanent luminescence is an effect of radioactivity.

H. Becquerel, and J. Becquerel found that at low temp. the bands of the uranyl phosphorescent spectrum, like those of the absorption spectrum, become sharp, so that the simple diffuse bands of uranyl nitrate at ordinary temp. become, in liquid air, intense narrow double bands between which other weaker bands appear. Potassium uranyl sulphate and especially the chloride give groups of bands, which, in liquid air, are resolved into fine intense bands arranged similarly in each spectrum. It is assumed that the phosphorescence is localized in the uranyl radicle. H. and J. Becquerel and II. K. Onnes found that the bands which are characteristic of the uranyl salts at the ordinary temp., and undergo subdivision at the temp. of liquid air, are transformed into groups of much finer lines at the temp. of liquid hydrogen. At the same time the emission maxima are displaced towards the smaller wave-lengths. Since the displacement is relatively small when the temp. falls from that of liquid air to that of liquid hydrogen, it is possible that the bands approach asymptotically a limiting position as the temp. is lowered. It is concluded that the difference between the frequencies of two successive homologous bands is practically constant, and this holds for all series of homologous bands of the same salt. For different uranyl salts the values of this constant differ but slightly from one another. In structure the uranyl salt bands resemble the band spectra of gases. At the temp. of solid hydrogen a strong magnetic field has no influence even on the narrow bands. The phosphorescence of the uranyl salts is quite different in character from that of other classes of phosphorescent substances, and in no way depends on the presence of traces of impurities. The transfer of electrons under the photo-electric influence of the absorbed light appears to be a process which is entirely confined to the uranium atom, or at least to the uranyl group. Observations on the phosphorescent spectra of uranyl salts were also made by E. L. Nichols, E. L. Nichols and E. Merritt, J. Moir, R. M. Müller, E. Goldstein, E. Wiedemann and G. C. Schmidt, O. Lommel, M. Cantone, S. J. Wawiloff and V. L. Levschin, S. J. Wawiloff, H. C. Jones and W. W. Strong. H. Becquerel observed similar phenomena with glass coloured by uranium oxide. O. Lommel also studied the phosphorescence of glass. L. de Boisbaudran observed that alumina is not made fluorescent by uranium salts. H. and J. Becquerel and H. K. Onnes found that the fluorescence spectra consist of three to eight regularly spaced groups, lying between bluish-green and red. Each group consists of about five components, which are separated on cooling and whose number then is augmented by numerous less regularly appearing lines. The distance in the scale of frequencies between homologous components is constant over the whole of the fluorescence spectrum of one definite substance. The absorption spectra, too, show a regular structure. The constant frequency interval between homologous components here has another, invariably smaller, value than in the fluorescence. When one considers the spectra of one substance one gets the impression that every series of fluorescence lines is prolonged towards the violet in a corresponding absorption series. F. Perrin and R. Delorme discussed the duration of the fluor-escence of uranyl salts. S. J. Wawiloff and V. L. Levschin observed that the luminosity of a soln. of uranyl sulphate in sulphuric acid continues for 10^{-5} to

10^{-4} sec. after illumination, and fades approximately exponentially. A rise of temp., or the addition of water, shortens the duration of luminosity. A. C. S. van Heel studied the various spectra of uranyl compounds in terms of the theory of transitions from various energy states or levels. E. L. Nichols and M. K. Slattery studied the photo or cathodic luminescence produced by traces of uranium in various salts—sodium and potassium phosphates, borax, and sodium and calcium fluorides.

The **triboluminescence** of oxides and sulphides has been discussed by A. Karl;[6] and of uranium salts, by J. A. Siemssen. The salts appear luminous when shaken or struck in the dark.

The high frequency or **X-ray spectrum** of uranium has the absorption limit 0·1075 for the K-series, which was studied by W. Duane and co-workers,[7] J. Schrör, M. de Broglie, B. Walter, H. R. Robinson and C. L. Young, G. Réchou, E. Frimann, J. E. Mack and J. M. Cork, and by M. Siegbahn and E. Jönsson. The L-series has lines a_2a^1, 0·92014; a_1a, 0·90833; $\beta_1\beta$, 0·71807; $\beta_2\gamma$, 0·75268; $\gamma_1\delta$, 0·61283; 1ϵ, 1·06477; η, 0·8029; $\beta_5\zeta$, 0·72413; $\gamma_2\theta$, 0·6044; β_4v, 0·7454; $\beta_3\phi$, 0·7084; $\gamma_3\chi$, 0·597; and $\gamma_4\psi$, 0·5738, with the absorption limits 0·7214, 0·5918, and 0·5685. The L-series was studied by M. de Broglie, J. Zahradnicek, A. Sandström, J. H. Williams, S. Idei, D. Coster, E. Hjalmar, A. Dauvillier, G. L. Clark, S. K. Allison, H. R. Robinson and C. L. Young, H. R. Robinson, H. Hirata, S. K. Allison and V. J. Andrew, J. Schrör, H. Brauns, and M. Siegbahn. The M-series includes a_1, 3·916; a, 3·9014; β, 3·7083; γ, 3·4714; δ, 2·943; and ϵ, 2·813, or M_1, 3·491, M_2, 3·326, and M_3, 2·873. They were studied by G. Wentzel, F. R. Hirsh, E. Lindberg, H. R. Robinson and C. L. Young, and D. Coster. The N-series, studied by V. Dolejsek, includes N_7P_1, 8·594; N_7P_2, 8·700; N_7O_3, 10·080; N_6O_2, 9·876; N_6O_5, 12·856; N_5O_1, 12·777; and N_5O_2, 12·702. The N-series, the O-series, and the P-series were also studied by H. R. Robinson and C. L. Young. W. Herz gave $3·13 \times 10^6$ for the **vibration frequency**. T. E. Aurén found that the relative at. absorption coeff. for X-rays is 1123 when that of lead is 569, and that of water, unity. S. J. M. Allen studied this subject. S. J. M. Allen, W. Duane and co-workers, and E. C. Stoner and L. H. Martin made observations on the absorption of X-rays by uranium; and R. W. James and G. W. Brindley, on the scattering of X-rays. H. R. Robinson and A. M. Cassie studied the secondary X-rays from a target of uranium oxide bombarded by a beam of K-rays; H. B. Wahlin, the emission of positive ions by the heated metal.

In 1804, A. F. Gehlen[8] found that an ethereal soln. of uranium chloride is decomposed in sunlight, and J. Fiedler, in a dissertation with the motto: *Nihil luce obscurius*—Nothing is darker (*i.e.* less known) than light—said that uranic chloride in the presence of organic substances is reduced to uranous chloride. A. E. Becquerel, and P. L. Chastaing observed that alcoholic soln. of uranyl nitrate, in light, deposit green uranous oxide, and J. J. Ebelmen observed a similar thing with alcoholic soln. of uranyl sulphate. H. C. Bolton observed that uranyl salt soln. in the presence of glycerol are reduced by light; A. St. V. Niépce, and E. Boivin observed the same thing in the presence of tartaric acid; C. J. Burnett, and A. St. V. Niépce, in the presence of paper. Many organic uranyl salts are reduced in light—*e.g.* A. St. V. Niépce and L. Corvisart, W. C. Holmes, W. Seekamp, C. J. Burnett, and D. von Monckhoven found this to be the case with uranyl oxalate and its double salts; A. St. V. Niépce and L. Corvisart, and L. L. Bonaparte, R. E. Liesegang, with the acetate, citrate, formate, tartrate, aconitate, etc.; and G. Courtois, with aq. soln. of uranyl propionate, butyrate, lactate, quinate, salicylate, oxalate, and tartrate are stable in the dark but not in light; whilst soln. of the acetate, formate, benzoate, glycollate, and citrate decompose in darkness and in light. G. Wisbar found that in light the presence of uranyl salts induces the decomposition of glutaric and succinic acids; W. C. Pierce and co-workers, malonic acid; W. G. Leighton and G. S. Forbes, and H. Fay, acetic, propionic, isobutyric, oxalic, malonic, tartaric, and succinic acids; J. C. Ghosh and B. N. Mitter, these

acids and in addition lactic, glycollic, and mandelic acids; T. Pavolini, hydroxy-acids; R. Luther and J. Plotnikoff, R. H. Müller, W. P. Jorissen, and W. P. Jorissen and L. T. Reicher, oxalic acid—P. F. Bacon, W. T. Anderson and F. W. Robinson, J. E. Moss and A. W. Knapp, P. F. Büchi, and E. Baur proposed the photolysis of oxalic acid in the presence of uranyl salts as a standard for measurement; E. Baur, and E. C. Hatt, formic acid; H. von Euler, acetic acid; J. Plotnikoff, hydriodic acid; H. Kunz-Krause and P. Manicke, iodic acid; J. C. Ghosh and J. Mukherjee, leucomalachite; J. Aloy and A. Valdiguié, dextrose, methylene-blue, aldehydes, the lower fatty alcohols, olefinic hydrocarbons—amylene, acetylenic hydrocarbons, cyclohexenes, toluenes, xylenes, cymene, chloroform, bromoform, iodoform, aliphatic ethers, aliphatic aldehydes, aromatic aldehydes (slow), ketones (slow), fatty acids—while the sat. hydrocarbons, cyclohexanes, benzene, phenols, amines, amides, and the phenolic ethers do not react; A. J. Allmand and L. Reeve, lactic acid; and D. Berthelot and H. Gaudechon, maleic, fumaric, pyruvic, and lactic acids. C. Neuberg observed the following changes occur in the presence of uranium salts, in sunlight: alcohols to aldehydes; poly-alcohols to hydroxy-aldehydes or ketones; acids to aldehydes or keto-compounds, sometimes with fewer carbon atoms than the original substance; monosaccharides to osones; disaccharides undergo inversion; polysaccharides and glucosides are hydrolyzed; amino-acids undergo deamidisation and lose carbon dioxide, yielding aldehydes with a smaller number of carbon atoms than the original substance; glycerides are partly hydrolyzed; and peptones and proteins are partly hydrolyzed. D. Berthelot and H. Gaudechon observed that apart from salts of uranium, neither the fluorescent nor radioactive substances experimented with accelerated photochemical reactions. The accelerating influence of the uranium salts is limited to a special class of reactions, namely, the decomposition of open-chain acids, especially dibasic or complex acids. These are reactions which occur spontaneously in ultra-violet light, and under the influence of the catalyst they take place in visible light. The catalyst thus lowers the vibration frequency of the photochemical reaction, in the same way as an ordinary catalyst lowers the temp. of a chemical reaction. P. L. Chastaing, and J. M. Eder observed that blue and violet light are most active in promoting these photolytic reactions; and, in agreement, N. Titlestad showed that light of wave-length between 4840 and 4230 is most active. According to J. Aloy and E. Rodier, when, under the influence of light, uranyl salts are converted into uranous salts in the presence of the acid entering into the constitution of the salt and a readily oxidizable substance such as alcohol, the reaction which occurs is as follows: $UO_2Cl_2 + 2HCl + C_2H_5.OH = UCl_4 + CH_3.CHO + 2H_2O$. Two mols. of acid are necessary for each mol. of uranyl salt. In this way uranous fluoride, chloride, bromide, iodide, and sulphate have been prepared, and an aq. soln. of the nitrate. If an insufficient amount of acid is present, basic salts are obtained. If the reaction is allowed to proceed further, a black precipitate of uranous hydroxide is obtained.

E. Baur and co-workers found that the reactions are accelerated by substances which destroy fluorescence; when all the uranyl salt has been reduced, fluorescence ceases. Consequently, the two phenomena appear to be connected. When light is absorbed by a soln. of a uranium salt, the uranyl ion undergoes a reversible change from the " dark " condition into the " light " condition; when the reverse action takes place, the light energy absorbed is given off again in the form of fluorescence. The addition of certain substances, such as chlorine or iodine ions, ferric and vanadyl salts, vanadic acid, and quadrivalent uranium salts, extinguishes the fluorescence. The same substances also destroy the Becquerel effect. In the sexivalent stage the uranium absorbs light energy, forming octovalent and tervalent uranium: $5U^{VI} + \text{Light} \rightarrow 3U^{VIII} + 2U^{III}$. If any substance is present with which the activated uranium can react, it does so, and reduction occurs; but if not, the reaction is reversed, and the uranium reverts to the " dark " condition, and fluorescence occurs. The reverse reaction is prevented by the presence of substances

which destroy fluorescence—*e.g.* reducing agents like oxalic acid, potassium iodide, and uranous salts which react with octovalent uranium; or oxidizing agents like ferric salts which react with the tervalent uranium. E. C. Hatt said the hypothesis that the light produces compounds of higher and lower valency is rendered probable by the fact that the insolated soln. have an oxidizing action on potassium iodide and a reducing action on potassium permanganate. In the photolysis of uranyl formate, the liberation of carbon dioxide and hydrogen is supposed to be due to the octovalent uranium; and the reaction dies down through the accumulation of sexavalent uranium, which acts as an extinguisher. In the photolytic decomposition of oxalic acid by uranyl sulphate, the octovalent uranium produces carbon dioxide, and tervalent uranium, carbon monoxide, while sexavalent uranium is re-formed. The products of the reaction are found to be formic acid, carbon dioxide, and carbon monoxide. The amount of formic acid formed is very small, and it is held that it must remain small, because it is used up as fast as it is produced in reducing the uranyl-ion to uranous-ion. The gas evolved contains a slight excess of carbon dioxide above that required for the simple stoichiometric relationship $CO_2 : CO$. The formation of formic acid is regarded as a cathodic reduction of carbon dioxide, thus: $CO_2 + 2H^· + 2\ominus = H.CO_2H$. The hydrogen reported to be formed in the photolysis of oxalic acid was shown by E. Baur and A. Rebmann to be carbon monoxide derived from glyoxylic acid present as an impurity. In the photolysis of uranyl acetate two reactions occur: (i) the photocatalytic decomposition into methane and carbon dioxide observed by H. Fay; and (ii) the non-catalytic oxidation of acetate-ions to ethane and carbon dioxide by uranyl salts, which only occurs in acetic acid soln. with a sufficient concentration of acetate-ions. The photolysis is favoured by the presence of free acetic acid, but is restricted by chloride ions and mercuric ions to some extent, and almost entirely by ferric salts or formic acid. The reaction cannot be regarded as a unimolecular decomposition of a uranyl acetate complex by light, but as an action of an activated uranyl complex on the surrounding molecules by an interchange of electrons. The process is an oxidation-reduction reaction and is therefore akin to electrolysis. Thus, in the electrolytic decomposition of acetate, acetyl peroxide and atomic hydrogen are the respective anodic and cathodic products, which then interact and form methane and carbon dioxide. Since the photolytic oxidation of acetic acid to ethane and carbon dioxide, and of glyoxylic acid to carbon monoxide and carbon dioxide, can be reproduced electrochemically only by the use of a considerable potential difference, it is concluded that the energy quantum absorbed by the uranyl complex must also have such a value as would suffice, not only for the production of oxygen, but also for the formation of peroxides, observed by A. Bach, and F. L. Usher and J. H. Priestley. In the photolysis of carbon dioxide in the presence of a uranyl salt, F. L. Usher and J. H. Priestley observed that formic acid is produced, with formaldehyde probably acting as an intermediate product, but E. Baur did not accept the observation. W. R. G. Atkins and H. H. Poole, M. Plotnikoff, and R. H. Müller made observations on the subject.

E. Baur found that the potential at a platinum electrode immersed in a soln. containing both uranous and uranyl salts is less positive in sunlight than in darkness; consequently, if two platinum electrodes are immersed in a soln. of the mixed salts so that one electrode is in darkness while the other is exposed to a bright light, the cell can be made to furnish a current—**Becquerel effect.** The displacement of the potential is considerable, and takes place more or less rapidly according to the nature of the salts employed. N. Titlestad immersed platinum electrodes in a soln. containing both uranous and uranyl sulphates, and the potential difference is measured when one electrode is illuminated and the other kept in darkness. In darkness, the e.m.f. of uranous-uranyl cells is represented by the equation: $E = e + RT/2F . \log_e [UO_2^{··}][H^·]^4/U^{····}$, corresponding with the chemical change: $UO_2^{··} + 4H^· \rightarrow U^{····} + 2H_2O + 2F$. e is 0·404 volt more positive than the normal

hydrogen electrode. Illumination displaces the potential towards the negative side, but this effect is observed only with smooth electrodes. The displacement of potential is approximately proportional to the logarithm of the light intensity. Some results are illustrated by Fig. 4 for light of relative intensities 4, 1, and 0·25 with soln. containing 75 mols of uranous sulphate and 25 mols of uranyl sulphate, at 25°. The initial velocity of the displacement of equilibrium on illumination is proportional to the intensity of the light. The velocity of displacement is practically independent of external circumstances, but the velocity of return increases with increasing concentration and temp., and with diminution in the sulphuric acid concentration. From these results it follows that the law of mass action does not apply to such cells. Small amounts of alcohol affect the light potentials slightly. On repeated illumination, the electrodes become slightly more positive. According to A. Samsonoff, uranous salts alone give no photoelectric current, and with uranyl salts the presence of traces of uranous salts is necessary for the effect. In the photoelectric cells indicated above it is assumed that the ions which result from the removal of electrons by the action of the light diffuse to the electrodes at different rates. The maximum effect is obtained when the incident light corresponds with the region of maximum absorption. In the continual action of the light rays, fatigue effects are exhibited, and when the light is removed, after-effects are observed. It is supposed that the photoelectric effect is not a consequence of, but rather the preliminary stage in, the chemical changes which occur under the influence of the light. The assimilation of carbon dioxide by plants is supposed to be accompanied in the same way by a previous formation of electrically charged mols. G. Trümpler found that the photochemical effect with uranous and uranyl salt soln. may show negative or positive effects according to the conditions; the former is attributed to the formation of quinquevalent uranium, and the latter to the presence of octavalent uranium in the illuminated region. Both stages are formed by the action of light on the uranyl salt. The negative effect is weakened by the presence of iodine, hydriodic acid, vanadium sulphate, vanadyl sulphate, hydrochloric acid, ferric sulphate, and ferrous sulphate. The positive effect is weakened by the presence of sulphur dioxide, uranous sulphate, and oxalic acid. All the substances which have a weakening action of the positive or negative Becquerel effect also reduce the fluorescence of uranyl sulphate soln. The fluorescence of these soln. is also decreased by an increase in the temp. H. Schiller studied the Becquerel effect with the uranium formates and oxalates; T. Pavolini, and A. Goldmann also studied the photoelectric effect; and S. J. Wawilow and W. L. Lewschin, the photoluminescence.

FIG. 4.—The Effect of Light of Different Intensities on the Photoelectric Effect.

H. Müller [9] found that the exposure of uranium to intense α-rays produced no effect on the induced radioactivity. A. Nodon found that the photogenic radiations emitted by the sun can penetrate metals of high valency, like lead or uranium, but not those of low valency, like magnesium, zinc, aluminium, or iron. M. de Broglie examined the α-ray spectrum. S. Maracineanu observed that after exposure to sunlight the activity of uranium oxide shows marked variations, which may amount to as much as 50 per cent. of the total activity. If the uranium oxide is exposed simultaneously to sunlight and to bombardment by the α-particles from polonium, the variations after exposure are more frequent than for sunlight alone. J. Thibaud studied the β-ray spectra and the photoelectric effect; J. Lifschitz and S. M. Hooghoudt, the Becquerel effect with soln. of uranyl salts; B. Gudden, the range of the α-particles from uranium; W. M. Cohn, the luminosity in cathode rays; F. Lotze,

the pleochroic uranium haloes. For the **radioactivity of uranium,** *vide* radium, **4.** 26, 126.

C. Benedicks [10] said that the sp. **electrical resistance** of uranium is less than that of bismuth, being about $62 \cdot 0 \times 10^{-6}$ ohms at 18°. P. W. Bridgman found the resistance to be 0·000076 ohm at 0°. This is high for a metal, being of the order of the resistance of liquid mercury and of bismuth. The temp. coeff. of the resistance between 0° and 100° is 0·00230. The resistance was found to decrease under press., as is normal for most metals. The average press. coeff. over the range 0 to 12,000 kgrms. per sq. cm. was $-0 \cdot 0_5 436$. A. Schulze made some observations on this subject. W. Meissner and B. Voigt, and J. C. McLennan and co-workers measured the electrical conductivity at low temp.; and W. Meissner and B. Voigt obtained for the ratio r of the resistance R_0 at 0° to the resistance R at the observed temp. when the value at 0° is $0 \cdot 0_2 6811$ ohm :

	0·16°	−186·20°	−195·47°	−252·59°	−268·80°	−271·59°
r	1	0·7001	0·6844	0·5867	0·5445	0·5400

According to C. Dittrich, the difference between the μ_{32} and μ_{1024} conductivities of soln. of uranyl chloride, nitrate, or sulphate is abnormally high presumably because ionization occurs in stages ; the conductivity increases appreciably with time owing to hydrolysis. The formation of acid $H^{\cdot}$-ions by hydrolysis is demonstrated by the effect of the soln. on the inversion of sugar. Some uranyl salts—*e.g.* the oxalate—show a diminished conductivity on exposure to light owing to the photolysis of the soln. The **transport number** of the uranyl-ion is 56 at 25°. Uranyl salts of weak acids have a marked tendency to form complex ions. This is shown by the fact that the sp. conductivities of the mixed sodium and uranyl salts are in most cases less than those of the sodium salts themselves : in the case of the oxalate, tartrate, and citrate, the specific conductivity of the mixture decreases with increasing concentration of the uranyl salt. Migration experiments confirm the formation of complex ions, bècause whilst in mixed soln. of uranyl and sodium oxalates the uranium is transported to the anode, it goes to the cathode in a mixed soln. of uranyl and sodium chlorides. The direction seems to depend also on the concentration. The solubility of uranyl oxalate is increased by the addition of sodium oxalate—a further proof that a complex ion is formed. The mixture of uranyl nitrate with sodium salts of organic acids is in most cases accompanied by an absorption of heat.

H. Moissan, as indicated above, obtained uranium by the **electrolysis** of molten sodium uranium hexachloride. According to C. Luckow, E. F. Smith and co-workers, and E. F. Kern, the electrolysis of soln. of uranium salts does not furnish the metal under ordinary conditions, but the cathode product is a hydrated oxide in various stages of oxidation. The fact is employed for the electrolytic separation of uranium from uranyl salts, the hydrated oxide being converted by heat to the U_3O_8-oxide before weighing. F. W. O. de Coninck and M. Camo observed that in the electrolysis of soln. of uranyl nitrate containing traces of nitric acid, a deposit is not formed, or rather the deposit initially produced is dissolved in the acid. If 6 to 8 per cent. soln. of the nitrate are electrolyzed, black, pulverulent, pyrophoric uranium monoxide is formed, and it oxidizes to the orange hydrate, $UO_3.H_2O$, when dried in the water-oven. If a weaker current is employed, the canary-yellow hydrate, $U_2O_3.2H_2O$, and the orange-coloured hydrate, $U_2O_3.H_2O$, are formed. With some soln. a current of about one amp. gives a mixture of the yellow and orange hydrates ; with others the black oxide, U_4O_5, is obtained, along with one of its hydrates which is violet. The latter in a dry atm. slowly changes into the yellow hydrate. The black oxide, U_4O_5, is very stable, and is thus distinguished from the monoxide ; it does not oxidize at 100°, and when strongly heated in hydrogen is reduced to the monoxide. According to C. A. Pierlé, in aq. soln. with low current density, uranyl salts deposit, in the first place, hydrated uranic oxide, $UO_3.H_2O$, which is changed as the electrolysis proceeds to a black oxide of varying

composition. With higher current density, uranyl sulphate is reduced to uranous sulphate, but in the presence of free acid the deposit obtained is small in amount and poorly adherent, although metallic in appearance. In neutral or alkaline soln., the deposit formed is a mixture of black and yellow oxides. The use of a diaphragmed cell does not change the character of the deposits. The deposit obtained when alkaline uranyl tartrate or citrate soln. are electrolyzed is an oxide much richer in uranium than that deposited from soln. acidified with tartaric or citric acid. Soln. of potassium uranyl fluoride, whether acid, alkaline, or neutral, form a deposit containing fluorine ; in acid soln. the deposit is $UF_4.6H_2O$; neutral and alkaline soln. give a deposit containing uranium tetrafluoride and uranium oxide. Deposits obtained from neutral soln. of potassium uranyl cyanide consist of pure potassium uranate. When acidified with hydrocyanic acid, the deposit is the yellow hydrated oxide contaminated with a little of the black oxide.

C. A. Pierlé added that the black deposit formed when uranyl salt soln. are electrolyzed is not $U_3O_8.2H_2O$, as reported by E. F. Smith, but rather $U_3O_{10}.2H_2O$, which has a potential different from that of U_3O_8. C. A. Pierlé found that the electrical conductivity of non-aqueous soln. of uranyl salts is a function of the water present, and the deposits formed are oxides contaminated with organic matter. Anhydrous pyridine dissolves anhydrous uranium tetrachloride to form conducting soln. ; these, on electrolysis, deposit a compound containing uranium and pyridine on the cathode. Soln. of uranium tetrachloride in acetone do not yield metallic uranium on electrolysis ; the soln. is a good conductor of electricity. The deposit obtained replaces mercury from mercurous sulphate. Uranium tetrachloride reacts with anhydrous acetone, forming $\beta\beta$-dichloropropane. During electrolysis, hydrogen is evolved. R. Groves and A. S. Russell studied the electrodeposition of uranium on mercury. U. Sborgi found the **electrochemical equivalent** of uranium, from soln. of the tetrachloride, to correspond with the at. wt. 240.

W. Muthmann and F. Fraunberger found that the **electrode potential** of a fresh surface of uranium in contact with N-KCl is -0.46 volt. Unlike the case of chromium, molybdenum, and tungsten, they observed no evidence of the **passivity** of uranium. U. Sborgi examined the anodic behaviour of uranium ; in some cases a little carbon dioxide was evolved—it was derived from the presence of a small proportion of carbon as impurity in the metal. The anode dissolved in sulphuric acid and sulphates, nitric acid and nitrates, hydrochloric acid and chlorides, bromides, acetates, and chlorate. In iodides separation of the halogen was also observed. In all the experiments except three the metal dissolved as though it had the valency four, but in some cases allowance has to be made for the evolved gas. In two experiments with sulphates and in one with nitrates the results indicated a valency of six. In phosphates and in alkalies the electrode was covered with a yellow deposit, and the current fell to a minimum ; when the deposit was mechanically removed at frequent intervals, the result agreed with the valency four. There was no evidence of uranium becoming passive. A. Günther-Schulze discussed the electrolytic valve action. A. Fischer and E. K. Rideal found that with an alcoholic soln. of uranium tetrachloride, the potential for U/U···· is 0.30 volt, and when this is calculated for aq. soln. from the difference for copper in aq. and alcoholic soln., the electrode potential becomes 0.23 volt. This allocates uranium's place in the electrochemical series between copper and hydrogen. This cannot be right, because uranium decomposes water and reduces soln. of stannous chloride. Its potential must therefore approach that of a baser metal, and they added that it probably lies between -0.4 and 0.2 volt. P. Herasymenko found the reduction potential of uranyl salts $U^{VI}=U^V$ for 10-fold dilution to be -0.056 volt. Powdered oxides fixed on to platinum with gelatine were found by C. A. Pierlé to have the following potentials : $U_3O_8/UO_2(NO_3)_2$, 14.3 grms. per litre$=0.776$ volt ; $UO_3.H_2O/UO_2(NO_3)_2=-0.860$; black oxide from aq. uranyl salts $/UO_2(NO_3)_2=-0.6872$ volt ; uranium 91.49 per cent. $/UO_2(NO_3)_2=-0.093$ volt. Uranous oxide, UO_2, gives a single potential identical with that obtained

for the green oxide, U_3O_8. W. Ogawa noted that uranium activated galena as a radio-detector. E. Z. Stowell studied the behaviour of uranium as cathode in the oscillating arc ; and M. Haitinger, the intensity of the ultra-violet rays from a uranium arc light.

H. Moissan [11] said that uranium is not magnetic when it is free from iron, but more precise measurements show that it is probably slightly paramagnetic. K. Honda found a specimen with 0·23 per cent. of iron had a **magnetic suscepti- bility** of $4·34 \times 10^{-6}$; and M. Owen gave $3·26 \times 10^{-6}$ mass unit. S. Meyer gave $0·21 \times 10^{-6}$ for the atomic magnetization (gram-atom per litre). P. Pascal found that the mol. magnetic susceptibility of the uranium ion decreases proportionally with an increase in its degree of oxidation, thus, the value for $U(SO_4)_2$ is 320×10^{-5}, and for $UO_2(SO_4)_2$, $-5·57 \times 10^{-5}$. S. Freed and C. Kasper studied the magnetic susceptibility of uranyl ions. D. M. Bose and H. G. Bhar found that the suscepti- bilities of salts of sexivalent uranium are diamagnetic.

§ 6. The Chemical Properties of Uranium

Uranium is fairly reactive chemically ; and in many of its properties it resembles iron. H. Moissan [1] found that **argon** has no action on the metal at a high temp. F. Fischer and F. Schrötter observed no reaction when uranium is electrically disintegrated under liquid argon. A. Sieverts and E. Bergner observed that neither argon nor **helium** shows a measurable solubility in uranium. No compound with **hydrogen** has been prepared ; but A. Sieverts and E. Bergner found that 100 grms. of metal at 1100° and 760 mm. absorb 1·6 mgrms. of hydrogen. G. Hägg studied the mol. vol. E. M. Péligot found that the metal is stable at ordinary temp. in dry **air**. J. Férée's pyrophoric uranium has been discussed above ; G. Chesneau found that the sparks detached from uranium by friction with hard steel instantly ignite mixtures of methane and air, so that the temp. of the sparks cannot be less than 1000° ; they also ignite alcohol, benzene, or light petroleum which has been poured on cotton. Sparks detached from steel by flint ignite none of these vapours and gases. J. L. C. Zimmermann found that the metal is slowly oxidized by exposure to ordinary atm. air ; and R. W. Moore added that it is considerably tarnished after a few days' exposure to air. J. Aloy observed that in moist air the surface of the metal becomes dull or matte. E. M. Péligot found that when the metal is feebly heated in air it burns with a brilliant white flame, and swells up to form uranium tritaoctoxide, and J. L. C. Zimmermann added that the ignition temp. in air or **oxygen** is between 150° and 170° ; H. Moissan said that it ignites in oxygen at 170°. The ignition temp. must depend on the state of subdivision of the metal. A. Burger made observations on this subject. E. M. Péligot found that if the powder be strewn through the flame, it burns showing brilliant sparks ; whilst H. Moissan observed that if molten uranium be dropped on to porcelain, or if fragments are shaken up in a glass vessel, brilliant sparks are produced owing to the combustion of a small amount of metal. There results, but with far greater brilliancy, a phenomenon analogous to that of the combustion of iron particles which catch fire by simple friction in the air.

E. M. Péligot said that uranium does not decompose cold water, but H. Moissan observed that if finely powdered, the metal slowly decomposes cold water, but more quickly at 100°; reduced iron also decomposes boiling water. Uranium which has been previously fused quickly acquires a layer of oxide when in contact with water, and the action is considerably quickened if carbon dioxide be present. D. Lely and L. Hamburger noticed that uranium is stable towards water and alkali-lye; and J. L. C. Zimmermann found that uranium is not perceptibly attacked by soln. of potassium or sodium hydroxide.

According to H. Moissan, electrolytic uranium catches fire in **fluorine,** burning brilliantly to produce a green volatile fluoride. O. Ruff and A. Heinzelmann found that the tetrafluoride which is formed is accompanied by a small proportion of hexafluoride. E. M. Péligot also said that finely-divided uranium burns in **chlorine** with the evolution of much light and heat to form the tetrachloride. J. L. C. Zimmermann gave 150° for the ignition temp. in chlorine, and added that a layer of chloride forming on the surfaces of the grains protects the interior from chlorination; but H. Moissan gave 180° for the ignition temp. in chlorine, and added that the reactions with chlorine and with the other halogens are all complete. J. L. C. Zimmermann gave approximately 240° for the ignition temp. in **bromine,** and added that the metal burns without incandescence and is partially converted to the tetrabromide; while H. Moissan gave 210° for the ignition temp. in bromine vapour, and added that the combustion proceeds with incandescence. J. L. C. Zimmermann found that **iodine** vapour attacks uranium with difficulty, forming the tetraiodide; whilst H. Moissan gave 260° for the temp. at which the iodide is formed with incandescence. J. Aloy observed that electrolytic uranium is easily attacked by iodine. Uranium is attacked by **hydrogen chloride** at a dull red-heat, forming a stable chloride; and by **hydrogen iodide** at a red-heat. E. M. Péligot, and D. Lely and L. Hamburger found uranium to be soluble in dil. **hydrochloric acid,** forming uranous chloride and evolving hydrogen. J. L. C. Zimmermann found that in the cold, conc. and dil. hydrochloric acid of sp. gr. 1·19 and 1·11 attack uranium; the hydrogen is given off turbulently with the more conc. acid, and a hyacinth-red soln. of the trichloride is formed, which becomes a green soln. of the tetrachloride when shaken in air.

E. M. Péligot observed that boiling **sulphur** unites with uranium with incandescence; J. L. C. Zimmermann said that when uranium burns in sulphur vapour, the black disulphide is formed; and H. Moissan found that the reaction takes place at 500° to form a black sulphide which is slowly attacked by hydrochloric acid, giving off hydrogen sulphide. Uranium also combines with **selenium** with incandescence. E. M. Péligot, and D. Lely and L. Hamburger observed that uranium is dissolved by dil. **sulphuric acid,** giving off hydrogen and forming the uranous salt. J. L. C. Zimmermann found that dil. sulphuric acid, of sp. gr. 1·15, dissolves uranium slowly in the cold, and more rapidly when warm, forming uranous salt and hydrogen; conc. sulphuric acid, of sp. gr. 1·85, when heated forms sulphur dioxide with the finely-divided metal, but the metal which has been previously melted is attacked only slowly. M. G. Levi and co-workers found that the reaction with a soln. of **potassium persulphate** is fairly rapid, forming a yellow soln. and giving off a gas; the reaction is slower with a soln. of **ammonium persulphate.**

H. Moissan reported that uranium has a great affinity for **nitrogen,** and unless great care be taken to avoid the action of this gas during the preparation of the metal a certain amount of nitride will be formed. I. Zschukoff said that the two elements interact at 1000°. W. P. Jorissen and A. P. H. Trivelli observed that nitrogen is evolved when uranium is exposed to cathode rays. The nitrogen is derived from the presence of 0·94 per cent. of nitrogen in the metal—probably as nitride. Powdered uranium reacts with **ammonia** above a dull red-heat with incandescence, hydrogen is evolved, and a black powder is formed. J. L. C. Zimmermann observed no perceptible action with aq. ammonia. F. Haber

used uranium as a catalyst in the synthesis of ammonia (*q.v.*). F. Emich observed that when uranium is heated in **nitric oxide** it burns very brilliantly to the trita-trioxide. E. M. Péligot found that with dil. **nitric acid,** nitric oxide is evolved and uranyl nitrate formed ; and J. L. C. Zimmermann showed that the metal which has been previously melted is only slowly attacked by warm nitric acid of ·sp. gr. 1·305 ; but the powdered metal is vigorously attacked, forming nitric oxide and uranyl nitrate. Red, fuming nitric acid attacks the powdered metal vigorously in the cold, but the fused metal is attacked very slowly.

H. Moissan noted the ready formation of carbide when the metal is heated with **carbon.** J. L. C. Zimmermann noted that **acetic acid** of sp. gr. 1·065 has no perceptible action. C. Beindl mentioned uranium as a catalyst in the synthesis of hydrocyanic acid from nitrogen, hydrogen, and carbon monoxide. A. Korczynsky, and O. Schmidt discussed its use as a hydrogenation catalyst for organic substances. Uranium displaces the metals, in part even in the cold, from soln. of **copper sulphate, silver nitrate, gold chloride, mercuric nitrate, stannous chloride,** and **platinum tetrachloride**—with **mercuric chloride** a mixture of mercury and mercurous chloride is formed.

Some reactions of analytical interest.—Green soln. of quadrivalent uranium salts are readily oxidized to sexavalent uranyl salts ; and yellow uranyl salts are readily reduced to green quadrivalent uranium salts—say when warmed with zinc and sulphuric acid. No precipitation occurs when soln. of either type of salt is treated with **hydrochloric acid** and then with **hydrogen sulphide.** Quadrivalent uranium salt soln. with **ammonium sulphide** rapidly darken in colour, and when boiled give a black precipitate ; whilst uranyl salt soln. precipitate brown uranyl sulphide which is soluble in dil. acids and in soln. of ammonium carbonate. Quadrivalent uranium salt soln. with alkali-lye or aq. ammonia give a voluminous pale green precipitate of the hydroxide, insoluble in excess—the precipitate rapidly oxidizes in air ; uranyl salt soln. give yellow precipitates of the uranates—the precipitation is hindered by tartaric or citric acid, and hydroxylamine chloride, and in the case of aq. ammonia it is favoured by ammonium chloride. The precipitate is soluble in soln. of ammonium carbonate. **Mercuric oxide** precipitates the uranium completely from soln. of uranyl salts mixed with ammonium chloride. Quadrivalent uranium salt soln. give a pale green precipitate with **alkali carbonates or hydrocarbonates ;** the precipitate is soluble in an excess of the hydrocarbonate, and it is readily oxidized, while a soln. of **ammonium carbonate** produces a similar precipitate, soluble in excess. Uranyl salt soln. with these reagents give orange-yellow precipitates of the alkali uranyl carbonate which is soluble in an excess of the precipitant. Quadrivalent uranium is precipitated from soln. of its salts by **barium carbonate ;** and similarly with uranyl salt soln. Quadrivalent uranium salt soln. with **potassium ferrocyanide** give a yellowish-green precipitate which on oxidation becomes reddish-brown ; uranyl salt soln. give a reddish-brown precipitate, or in dil. soln., a brownish-red coloration which becomes yellow when treated with potassium hydroxide. Quadrivalent uranium salt soln. with **potassium ferricyanide** give a yellowish-green precipitate which quickly oxidizes to a reddish-brown substance ; **hydrofluoric acid** forms an insoluble fluoride. Uranyl salt soln. with **sodium hydrophosphate** give a precipitate of yellowish-white uranyl phosphate, or, in the presence of ammonium acetate, ammonium uranyl phosphate. Uranyl salt soln. give a precipitate of a peruranate with **hydrogen dioxide,** and with **sodium dioxide ;** the precipitate is soluble in an excess of the alkali dioxide. V. Auger [2] found that uranyl salts are not precipitated by **cupferron,** but if reduced to uranous salts by zinc and acid, precipitation occurs. J. A. Siemssen found that **ethylenediamine** with uranyl salt soln. gives a yellow crystalline precipitate. Uranyl salt soln., particularly the nitrate, colour **turmeric paper** brown ; and, according to H. J. H. Fenton, give a brown colour with **dioxymaleic acid.** J. H. de Boer discussed the violet coloration with **alizasinesulphonic acid.**

The physiological action of uranium salts.—G. C. Gmelin,[3] A. Rabuteau,

and C. le Conte showed that uranium salts are poisonous to the animal organism. B. Fischer and C. Hartwich say that uranium is included in the official lists of poisons in Germany and Russia, and that it is approximately as toxic as arsenic. J. Woroschilsky's observations on mammals, birds, frogs, and worms show that however administered uranium is a very poisonous metal. C. le Conte said that the most characteristic symptom of poisoning by uranium is the high sugar content of urine. R. H. Chittenden and M. T. Hutchinson showed that uranium salts have a marked inhibitory influence on the activity of digestive ferments; and R. H. Chittenden and A. Lambert showed that in experiments with uranyl nitrate on rabbits uranium is an irritant poison, and like other metallic irritants produces gastro-intestinal irritation of more or less intensity. But it is not in any sense a rapid poison, and the injection of a fatal dose is not followed by any noticeable effects for some time. The action of a small amount (0·15 grm.) seems to be as rapid and pronounced as that of a larger quantity (1 grm.). The first noticeable symptom is muscular weakness ; the salt checks digestion, but apparently increases proteïd metabolism to a slight extent : it increases the output of carbonic anhydride, raises the body temp., and finally leads to emaciation. In the kidney, a condition of acute nephritis and destruction of the renal tissue is found, like that produced in poisoning by arsenic, mercury, and phosphorus. Albuminuria is severe and constant. With small doses the volume of urine is increased, but when toxic action is pronounced there may be partial or even complete suppression of that secretion. The production of glycosuria generally occurs after that of albuminuria, but it is a very constant and characteristic symptom. The urine, in cases of uranium poisoning, invariably contains a large amount of crystallized calcium oxalate. In chronic poisoning by uranium, the nervous symptoms (loss of sight and of co-ordinating power) sometimes predominate, according to J. Woroschilsky, F. Cartier, D. E. Jackson and F. C. Mann, and R. Fleckseder, owing to the coagulating action of uranium salts, observed by N. Kowalewsky, A. Müller, and B. Szilard, on albumin. Conc. soln. of uranium salts corrode the mucous membrane, transforming the walls of the stomach into a dead film of uranic albuminate. The subcutaneous injection of a non-corrosive uranium salt produces glycosuria, with fatty degeneration of the walls of the blood-vessels and fatty changes in the liver and kidneys, so that the animal wastes and dies. The subcutaneous injection of 0·5 to 2·0 mgrm. of UO_3 per kilogram will kill a cat, dog, or rabbit. The nitrate or acetate introduced by the mouth produces gastroenteritis and nephritis, with hæmorrhages in the substance of the kidney.

O. Loew found that dil. soln. of uranium nitrate—say 0·1 per cent.—increased the yields of peas and oats, stimulating the production of straw and seed. Soln. with 0·2 per cent. of the salt poisoned young pea-plants in three days. J. Stoklasa found that with *melilotus albus*, the addition of an optimum quantity of 2·5 kgrms. per hectare of soil, had a favourable effect on the total yield of dry matter. There was no indication of any toxic effect with 20 kgrms. per hectare. C. Acqua observed that when plants are grown in soln. containing traces of uranyl nitrate, root growth is rapidly arrested owing to the penetration of uranium into the nuclei of the meristem. It can be seen there in the form of a yellow substance, probably the yellow oxide. The chromatin of these nuclei is found to have disappeared, so that karyokinetic division is no longer possible. According to P. Becquerel, there is an optimum dose with uranium salts which favours the maximum growth of the bacillus and above which they begin to exert a toxic effect. A dose of 1 in 2500 has a marked inhibitory influence. H. Agulhon and T. Robert found that colloidal uranium of conc. 1·2 : 10,000,000 to 6 : 100,000, prepared by electrical dispersion, has a much greater effect in increasing the activity of the pyocyanic bacillus than has powdered uranium. Although colloidal uranium is capable of accelerating the formation of pyocyanin for a race which produces it normally, it is incapable of producing the chromogenic function in cultures of races which are devoid of this function. H. Bechhold, and M. Neisser and U. Friedemann dis-

cussed the coagulating action of uranium salts on bacteria. W. Sigmund discussed the relation between the at. wt. and the degree of ionization on the physiological action of soln. of salts.

Some uses of uranium.—Very few of the applications of uranium at present known are of great industrial importance.[4] Uranium has been tried in the manufacture of lamp-filaments and gas-mantles ; [5] in the manufacture of iron alloys ; [6] in photometry ; [7] in photography for toning, etc. ; [8] as a dye or stain for textiles, leather, and wood ; [9] in medicine in the form of *Uranwein* for *diabetes mellitus* ; [10] as a colouring agent—*uranium yellow*—in the form of ammonium or sodium diuranate, for glasses, glazes, and enamels ; [11] as a reagent for phosphates, etc., in analysis ; and as a catalytic agent in chemical processes.[12]

§ 7. The Valency and Atomic Weight of Uranium

The early investigations of A. Schönberg,[1] J. A. Arfvedson, and J. J. Berzelius on the at. wt. of uranium are only of historical interest, because the dioxide was mistaken for the element. After the recognition of the true nature of the element by E. M. Péligot, in 1841, and his subsequent determination of the equivalent, it was assumed that the at. wt. was about 120, and the valency is 3. In 1872, D. I. Mendeléeff[2] pointed out that there is no place in the periodic table for a tervalent element of at. wt. 120, and he emphasized the resemblance in the properties of chromium, molybdenum, tungsten, and uranium considered as a family group. He therefore suggested that the at. wt. be doubled so that uranium could be placed below tungsten in the periodic table. He also represented the oxides of the element, by analogy with the other elements of the family, by the formulæ UO_2, U_3O_8, and UO_3, implying that the element can be quadrivalent and sexavalent. The position of uranium in the periodic table, and comparisons of the properties of uranium with those of other members of the family group were made by F. W. O. de Coninck, S. M. Losanitsch, H. E. Roscoe, A. von Grosse, W. Muthmann, H. Rossi, E. J. Mills, J. L. C. Zimmermann, O. F. von der Pfordten, M. M. Gerber, and G. Alibegoff. Isomorphism has very little to say about the relations of uranium with the other members of the family group. J. L. C. Zimmermann's determinations of the vapour density of uranium tetrachloride and tetrabromide, O. Ruff and A. Heinzelmann's determination of the vapour density of the hexafluoride, and L. Rügheimer's determination of the mol. wt. of the tetrachloride from its effect on the b.p. of bismuth trichloride favour the doubled at. wt., 240. Similarly with the sp. ht. rule; with U. Sborgi's determination of the electrochemical eq. of soln. of uranium tetrachloride; and with the high frequency or X-ray spectrum. The mass of evidence mounts to the altitude of proof that the at. wt. of uranium, in agreement with the prognostications of D. I. Mendeléeff, approximates 240; and that uranium is a member of the chromium, molybdenum, and tungsten family of elements.

The observations of O. Ruff and A. Heinzelmann on the vapour density of uranium hexafluoride establish the *sexavalency* of uranium; and since ammoniacal soln. furnish ammonium uranate, in which the trioxide, UO_3, appears as the anhydride of uranic acid, it is highly probable that uranium is sexavalent in this oxide, as well as in the uranyl derivatives, $UO_2(NO_3)_2$, etc. The existence of uranium pentachloride corresponds with a *quinquevalent* uranium, but the evidence is not unequivocal. The *quadrivalency* of uranium in the tetrachloride and tetrabromide has been established by the mol. wt. determination of J. L. C. Zimmermann, and L. Rügheimer, by the existence of the dioxide and disulphide, and by the isomorphism of thorium and uranium dioxides observed by W. F. Hillebrand, and of the disulphates observed by W. F. Hillebrand and W. H. Melville. A. Rosenheim and co-workers obtained a complex with pyrocatechol and quadrivalent uranium, namely $2\{(NH_4)_2[U(C_6H_4O_2)_3]\}C_6H_4O_2.8H_2O$. The *tervalency* of uranium is in agreement with the existence of the trihalides; and the *bivalency* with the existence of the difluoride, monoxide, and monosulphide—but the evidence is here not decisive. It is an open question whether uranium is *octovalent* in the tetroxide, UO_4, of P. G. Melikoff and L. Pissarjewsky.

Although the earlier attempts to determine the at. wt. of uranium were vitiated by the erroneous assumption that uranium dioxide was the metal, this does not affect the analytical data. The methods of purifying uranium, however, were not good, so that although the data can be adapted to the new knowledge about the nature of the element, the results of J. J. Berzelius,[3] J. A. Arfvedson, and R. F. Marchand are unsatisfactory. C. F. Rammelsberg's observations on the analysis of uranium tetrachloride vary so widely that they are best omitted when computing the general mean. There remain J. J. Ebelmen's determination of the ratio $UO_2(C_2O_4).H_2O : UO_2$ from which is calculated 238 for the at. wt. of uranium ; and his determination of the ratio $3UO_2 : U_3O_8$ gives 240. J. L. C. Zimmerman's value for the ratio $3UO_2 : U_3O_8$ gives the at. wt. 239·6 ; and his value for the ratio $Na(UO_2)(C_2H_3O_2)_3 : Na_2U_2O_7$ gives 240·2 ; I. Wertheim obtained 240 from the same ratio. E. M. Péligot obtained 240 from the ratio $CO_2 : U_3O_8$, and F. W. O. de Coninck 238·4 from the same ratio. P. Lebeau calculated the at. wt. 238·5 from the ratio $U(OH)_4(NO_3)_2 : UO_2$. J. Aloy obtained 239·4 from the ratio $N : UO_2$ prepared by igniting the nitrate, measuring the resulting nitrogen, and reducing the uranium tritaoctoxide. O. Hönigschmid and W. E. Schilz calculated 238·136 from the ratio $UCl_4 : 4Ag$, and 238·142 from the ratio $UCl_4 : 4AgCl$. T. W. Richards and B. S. Merigold calculated 238·4 from the ratio $UBr : 4AgBr$, and with the same ratio O. Hönigschmid calculated 238·09 to 238·18 ; and O. Hönigschmid and S. Horovitz, 238·05 to 238·17. From the ratio $UBr_4 : 4Ag$, T. W. Richards and B. S. Merigold calculated 238·4 ; O. Hönigschmid, 238·11 to 238·18 ; and O. Hönigschmid and S. Horovitz, 238·06 to 238·17. F. W. Clarke calculated 238·977 as the best representative value or the general mean of the results available up to 1910 ; and J. Meyer, 238·2 for the results available up to 1921. The International Table gives 238·2 for the best representative value. The at. wt. of uranium was discussed by A. S. Russell, and S. Meyer.

The **atomic number** of uranium is 92. Uranium is the last in the list of elements arranged according to their increasing at. wts. Thorium has the at. number 90 ; and the gap 91 is filled with the isotopes, protactinium and brevium. P. Vinassa discussed the molecular numbers. O. Hahn [4] discussed the **isotopes** of uranium ; F. W. Aston was unable to measure the mass spectrum of uranium in order to determine the isotopes. Both thorium and uranium are regarded as elements whose nuclei are so complex that they are only partially stable, that is, they are very slowly undergoing a process of degradation into simpler forms. The **electronic structure** on N. Bohr's system is : (2) for the K-shell ; (2, 6) for the L-shell ; (2, 6, 10) for the M-shell ; (2, 6, 10, 14) for the N-shell ; (2, 6, 10) for the O-shell ; (2, 6, 4) for the P-shell ; and (2) for the Q-shell. This subject was discussed by W. D. Harkins, C. D. Niven, P. D. Foote, J. D. M. Smith, and J. N. Frers. The spontaneous **atomic disintegration** of uranium has been discussed in connection with the radioactivity of uranium—**4**. 26, 10 and 11. Ordinary uranium is there shown to be a mixture of two isotopes, designated uranium-I and uranium-II, with the respective at. wts. 238·2 and 234·2. The one is spontaneously passing into the other by way of the intermediate stages uranium-X and uranium-X_2— vide **4**. 26, 10 and 11. The uranium-X, and helium in the form of α-rays, represent the products of the first stage in the spontaneous decay of uranium proper. E. Rutherford and J. Chadwick,[5] and H. Müller obtained negative results in the attempt to disintegrate the atom by bombardment with α-rays. The subject was discussed by G. I. Podrowsky. According to A. Gaschler, the radioactive transformation of uranium into uranium-X can be accelerated by an intense electric discharge. He said :

In a narrow vertical tube of fused quartz an electrode of tungsten was 15 cm. above a thin layer of uranium oxide resting on mercury in which was embedded the second tungsten electrode. The oxide was freed from all radio-active constituents before it was used. After frequent electrical discharges of 0·3 or 0·4 ampère had passed for thirty hours from one electrode to the other, definite and growing radio-activity manifested itself by the

presence of β-rays and γ-rays. Moreover, the radio-active material was separated by chemical means and its half-period when measured proved to be that of uranium-X. The β-ray and γ-ray activity of the uranium oxide freed from the mercury varied between 1·4 and 20 times the radio-activity of an equally large amount of uranium oxide in equilibrium with its decay products, and increased proportionally to the energy applied and to the time.

§ 8. The Intermetallic Compounds of Uranium

J. W. Marden and H. C. Rentschler [1] said that uranium readily alloys with metals—*vide supra*, uranium. Definite alloys of uranium with the alkali metals have not been reported, although A. Colani referred to alloys with sodium and potassium formed when uranous chloride is heated with an excess of these elements. H. Moissan [2] prepared some alloys of **copper** and uranium. Alloys with silver and gold have not been reported. A similar remark applies to alloys of uranium with the metals of the alkaline earths, beryllium, and cadmium. J. W. Marden obtained alloys with **zinc** by reducing mixtures of uranium oxide and zinc chloride by calcium. A. Colani referred to a binary alloy formed when uranous chloride is heated with an excess of **magnesium.** G. Tammann and J. Hinnüber [3] found that **mercury** dissolves 0·00014 per cent. of uranium at ordinary temp. J. Férée obtained an alloy with mercury—that is, *uranium amalgam*—by electrolyzing an aq. soln. of uranous chloride using a mercury cathode—*vide supra*, pyrophoric uranium. According to A. S. Russell and co-workers, uranium is deposited on zinc, tin, copper, or mercury when the liquid amalgam is shaken with an acidified soln.

A. Colani referred to the formation of a binary alloy when uranous chloride is heated with an excess of aluminium. L. Guillet prepared alloys with aluminium by the aluminothermite process. He used uranium oxide which he prepared from ammonium uranate. The ignition mixture consisted of barium dioxide and aluminium (4 : 1), which was ignited with a match. H. Moissan prepared the alloys by adding a mixture of aluminium powder and uranium oxide to molten aluminium ; part of the aluminium burns, and there is such an energetic development of heat that the oxide is reduced, and the metal alloys with the rest of the aluminium. J. Aloy prepared alloys by the electrolysis of molten potassium uranium hexachloride with an aluminium cathode. P. A. Heller found that the production of aluminium-uranium alloys by the thermite method gives a very poor yield, but satisfactory results may be obtained by reducing a mixture of uranyl fluoride and uranium tetrafluoride (formed by adding U_3O_8 to hydrofluoric acid) by means of metallic calcium in the presence of aluminium, the operation being conducted in an iron bomb. By this method an alloy containing 62·8 per cent. U, 34·8 per cent. Al, 1·4 per cent. Ca, 0·5 per cent. C, and 0·25 per cent. Si was obtained. L. Guillet considers that two intermetallic compounds are formed. **Uranium hemitrialuminide,** U_2Al_3, is obtained by the thermite process from a mixture of 110 grms. of aluminium and 390 grms. of uranium oxide. The cubic crystals are very hard. The compound is stable in air, but readily oxidizes when heated. At 450° to 500°, chlorine forms red needles of the pentachloride, and at a higher temp., uranium tetrachloride—including, of course, aluminium trichloride. Water forms a film of green oxide on the alloy ; and acids attack it readily. A mixture of 135 grms. of aluminium and 365 grms. of uranium oxide, by the thermite process, furnishes **uranium trialuminide,** UAl_3, in fine acicular, silver-white crystals. The sp. gr. is 5·32 at 20°. Their chemical properties resemble those of the hemitrialuminide.

H. Moissan prepared alloys of uranium and **titanium** by the method he employed for alloys with aluminium. A. Colani referred to a binary alloy with tin when an excess of that metal is heated with uranous chloride. J. A. Heany obtained an alloy with **vanadium.** H. Moissan, J. A. Heany, and A. Stavenhagen and E. Schuchard obtained an alloy with **molybdenum ;** and A. Stavenhagen and E. Schuchard the quaternary alloy U–Cr–Mo–Ti. J. W. Marden and H. C. Rentschler, and H. Moissan, alloys with **tungsten.** The Westinghouse Lamp Co. obtained uranium-tungsten alloys by shaking up a mixture of the finely-divided metals in a soln. of paraffin oil in ether, and then sintering them together.

§ 9. Uranium Dioxide and the Lower Oxides

The chief oxides of uranium are the dioxide, UO_2, and the trioxide, UO_3, with the intermediate oxide, U_3O_8. There are a few other less well-defined oxides which have been reported. C. Wagner and W. Schottey [1] discussed the system : uranium-oxygen. F. W. O. de Coninck and M. Camo found that the electrolysis of a 6 to 8 per cent. soln. of uranyl nitrate yields a black, pulverulent, pyrophoric oxide—possibly *uranium monoxide—vide supra*, the electrolysis of uranium salts. A similar substance was obtained by reducing the pentoxide with hydrogen at a high temp. These conclusions lack confirmation. The pale green soln. obtained by reducing uranyl salts with zinc gives a pale green precipitate when treated with alkali-lye, and the hyacinth-red soln. containing tervalent uranium also gives a pale green precipitate with alkali-lye. These products are supposed by A. Guyard to contain *uranium dihydroxide*. The conclusion is not supported by the observations of O. Follenius, A. Belohoubek, H. Hermann, and J. L. C. Zimmermann. According to E. M. Péligot, if a soln. of uranyl dichloride is reduced with zinc and hydrochloric acid, the hyacinth-red soln. contains uranium trichloride, and gives a brown precipitate—probably **uranium trihydroxide**, $U(OH)_3$—when treated with aq. ammonia. This rapidly oxidizes to green tetrahydroxide, and thence to ammonium uranate. J. L. C. Zimmermann discussed these observations. A. Rosenheim and H. Löbel also regarded the brown precipitate obtained by adding aq. ammonia to hydrochloric acid soln. of uranium trichloride to be uranium trihydroxide. Not infrequently reference is made in literature to **uranium sesquioxide, or hemi-trioxide**, U_2O_3 when, presumably, the trioxide is meant, and the old at. wt. 120 has been used. F. W. O. de Coninck and M. Camo said that they prepared the lemon-yellow *dihydrate*, $U_2O_3.2H_2O$, and the orange *hydrate*, $U_2O_3.H_2O$, and also black *uranium hemipentoxide*, U_2O_5, by the electrolysis of soln. of uranyl nitrate as indicated above. The chemical individuality of these electrolytic products has not been established.

The observations of M. H. Klaproth,[2] J. B. Richter, C. F. Bucholz, J. J. Berzelius, and A. Schönberg on the preparation of uranium by heating an intimate mixture of uranium oxide and carbon can be employed for the preparation of **uranium dioxide, or uranous oxide**, UO_2. The properties of the old uranium are properties of uranium dioxide. J. Aloy found that uranium dioxide is formed in the electric arc furnace when the temp. is not high enough to produce the carbide. P. Jolibois and R. Bossuet found that to convert uranosic oxide into the dioxide by simple dissociation, it must be heated at 2000° in vacuo—*vide infra*, uranosic oxide. W. Biltz and H. Müller recommended heating the uranosic oxide at 900° in hydrogen, when the product is brown ; if a dense form of uranosic oxide is used, the product is dark brownish-violet. By heating the uranosic oxide in vacuo, W. Biltz and H. Müller, unlike E. Friederich and L. Sittig, could not get nearer UO_2 than $UO_{2.15}$. Uranium dioxide was obtained by J. L. C. Zimmermann by

heating the tritaoctoxide in an indifferent gas—carbon dioxide or nitrogen; and A. Ditte showed that the transformation proceeds quickly if the oxide be moistened with a few drops of hydrofluoric acid, and that the trioxide in the presence of the vapour of hydrogen fluoride forms the dioxide. I. Wertheim heated a mixture of uranium tritaoctoxide and oxalic acid; J. J. Berzelius, and F. W. O. de Coninck, uranyl oxalate; and F. W. O. de Coninck, uranyl bromide, sulphite, or sulphate out of contact with air. J. A. Arfvedson, A. Laugier, and L. R. Lecanu obtained the dioxide by heating to redness uranosic oxide in a current of hydrogen. P. Jolibois and R. Bossuet said that the reaction commences at 625° and is completed at 650°. O. F. von der Pfordten, and P. Sabatier and J. B. Senderens similarly heated the trioxide to redness in hydrogen gas and obtained the dioxide; J. Aloy, uranyl hydroxide; F. W. O. de Coninck, uranium trioxide, or uranyl sulphate, chloride, or bromide; E. M. Péligot, and P. Lebeau, uranyl nitrate; J. J. Ebelmen, and H. Hermann, uranous sulphate; E. M. Péligot, and J. J. Ebelmen, the oxalate; and J. A. Arfvedson, potassium uranyl chloride—and washing out the potassium chloride and undecomposed salt with water. E. M. Péligot added that the oxide should be allowed to remain in hydrogen until the containing vessel is cold, owing to the pyrophoric properties of the dioxide, but J. J. Ebelmen said that if the temp. be cherry-red, the dioxide, after cooling in hydrogen, is stable in air; E. M. Péligot heated potassium uranyl chloride in the absence of air; and F. Wöhler heated the alkali salt with an excess of ammonium chloride, and washed the soluble matters from the resulting uranium dioxide. E. F. Smith and J. M. Matthews heated to whiteness for about 6 hrs. uranium tritaoctoxide mixed with a large excess of ammonium chloride in a porcelain crucible packed with charcoal in a larger fireclay crucible. A. Colani obtained the dioxide by passing steam in a current of carbon dioxide over heated sodium uranium hexachloride, and extracted the cold product with water. F. W. O. de Coninck heated uranyl chloride with powdered magnesium, aluminium, lime, or baryta out of contact with air, and washed the cold product with water. H. Rose melted uranyl phosphate with six parts of a mixture of equal proportions of sodium carbonate and potassium cyanide, and extracted the cold mass with water; uranium dioxide remained. J. J. Ebelmen reduced the hemipentoxide by heating it with sulphur; and H. Hermann reduced the hemipentoxide, and also sodium uranate, with sulphur and ammonium chloride, and he also heated uranosulphate with potassium pentasulphide at 200° in a closed crucible; in each case the products were washed with water. H. Hermann also reduced the tritaoctoxide and the trioxide by heating them in a current of carbon dioxide laden with the vapour of carbon disulphide. F. W. O. de Coninck obtained this oxide as a black powder by the electrolysis of a soln. of uranyl nitrate—*vide supra*.

K. A. Hofmann and K. Höschele prepared fine, black, cubic crystals of uranium dioxide by fusing together one part of sodium diuranate and 4 parts of magnesium chloride; and W. F. Hillebrand, by fusing uranium tritaoctoxide with borax for a long time. Amorphous uranium dioxide is similarly converted into the crystalline variety by fusion with borax.

A. Samsonoff prepared **colloidal uranium dioxide** by electrolyzing a soln. of uranyl chloride; it appears as a black precipitate at the cathode. The precipitate is soluble in water, giving a dark-coloured soln. which shows the presence of ultramicroscopic particles. A very dil. soln. has a yellow tinge, and the absorption spectrum indicates that neither a uranous nor a uranyl salt is present. In an electric field the soln. becomes decolorized at the anode, and precipitation takes place at the cathode. On addition of electrolytes, coagulation phenomena characteristic of the positive colloids are observed. The same substance is also obtained in the reduction of uranyl chloride by zinc or copper in dil. acid soln. Uranous chloride acts as a protector, and increases the stability of the colloidal soln. E. M. Péligot found that when alkali-lye or aq. ammonia is added to a soln. of a uranous salt, a reddish-brown gelatinous precipitate of the hydrated dioxide is

formed. The flocculent precipitate becomes black and compact when boiled. When the precipitate is dried in vacuo it approximates to the *monohydrate*, $UO_2.H_2O$. This rapidly oxidizes in air, and dissolves in acids to form uranous salts. J. Aloy obtained a black *dihydrate*, $UO_2.2H_2O$, or, possibly, **uranous hydroxide**, $U(OH)_4$, by the action of hot alkali-lye on crystalline uranous sulphate. The product when thoroughly washed can be kept for several days without perceptible change. When heated it passes into the green tritaoctoxide. It is soluble in dil. acids.

Uranium dioxide has been variously described as forming a black, crystalline powder (F. Wöhler); iron-grey needles (C. F. Bucholz); black, lustrous scales (E. M. Péligot); reddish-brown powder when free from nitrogen and chlorine (E. F. Smith and J. M. Matthews); reddish crystals which are transparent under the microscope (A. Colani); metallic powder consisting of microscopic, regular octahedra (J. A. Arfvedson); and E. M. Péligot, and J. Aloy, as a black, or brown, pyrophoric powder. E. Friederich and L. Sittig found that blue and brown forms are produced when uranosic oxide is heated over 1000° in nitrogen and hydrogen respectively. F. W. O. de Coninck observed that a brick-red variety is produced when uranyl bromide is heated in air; it is said to be very stable at high temp., and to pass into the black variety without loss of oxygen when it is heated in hydrogen. For the **colour** of the oxide, *vide infra*, uranium trioxide. L. Pauling discussed the crystal structure. W. F. Hillebrand, and A. Schoep found that the octahedral or cubic crystals are isomorphous with those of cerium and thorium dioxides. V. M. Goldschmidt and L. Thomassen found that the **X-radiograms** of uranium, thorium, and cerium dioxides correspond with a face-centred, cubic lattice with the oxygen atoms arranged probably on the calcium fluoride type. The edges of the unit cube are 5·47 A. for uranium dioxide, 5·41 A. for thorium dioxide, and 5·41 A. for cerium dioxide—*vide infra*, pitchblende. A. E. van Arkel gave $a=5·48$ A. W. Biltz and H. Müller made some observations on this subject. E. J. Cuy estimated the interatomic distances in the crystal to be 2·37 A. M. H. Klaproth gave 6·44 for the **specific gravity**; J. B. Richter, 6·94; C. F. Bucholz, 9·0; and J. J. Ebelmen, 10·15. A. Raynaud gave 8·2 for the sp. gr. of the dioxide prepared at 300°–320°. W. F. Hillebrand found that the crystals had a sp. gr. between 10·95 and 11·0 at ordinary temp., and referred to water at 4°. W. Biltz, and W. Biltz and H. Müller gave 10·82 at 25°/4° for the sp. gr. of the oxide which had been heated to 1300°; 24·97 for the **molecular volume**, and 6·15 for the at. vol. of the oxygen—*vide infra*, uranium trioxide, and uranosic oxide. H. V. Regnault gave 0·0619 for the **specific heat**. O. Ruff and O. Goecke found that the oxide has a **melting point** of 2196° in an atm. of nitrogen. E. Friederich and L. Sittig gave 2500°–2600° for the m.p. of the blue and brown dioxides. The great stability of this oxide misled the earlier investigators into the belief that they were dealing with a veritable element. For the **volatilization** of the dioxide, *vide infra*, uranium trioxide. E. Friederich and L. Sittig observed that when the dioxide, is heated on tungsten filaments in hydrogen or in nitrogen complete volatilization occurs in a few minutes. W. G. Mixter found the **heat of formation** to be $U+O_2=UO_2+256$ Cals.; and **heat of oxidation**, $UO_2+O=UO_3+34·2$ Cals. J. O. Perrine observed no fluorescence with **ultra-violet light**. J. Vrede studied the dioxide as a detector of **electromagnetic waves**. M. K. Slattery found that a trace of the dioxide added to many salts—*e.g.* sodium or lithium fluoride—renders them fluorescent in ultra-violet light. E. Friederich and L. Sittig found that when the powdered oxide is pressed into rods and then heated to 1000°, the sp. **electrical resistance** at room temp. of the blue dioxide is $30×10^3$ ohms per sq. mm., and that of the brown dioxide is $26·5×10^6$ ohms per sq. mm. M. le Blanc and H. Sachse gave for the sp. conductivity, K, of uranium dioxide:

20°	50°	100°	150°	200°	300°	400°	500°
K 2·4×10⁻⁴	4·0×10⁻⁴	1·0×10⁻³	5·0×10⁻³	1·0×10⁻²	2·5×10⁻²	4·0×10⁻²	7·0×10⁻²

C. A. Pierlé found the **electrode potential** of the black oxide is the same as for the

green uranium tritaoctoxide (*q.v.*). R. Luther and A. C. Michie found that uranous salts are strong reducing agents even in acid soln.; the oxidation by atm. oxygen is accelerated by iron salts, platinum black, and especially by copper salts. The difference of potential between a platinized platinum electrode and a soln. of uranous and uranyl salts in sulphuric acid is given by $\epsilon = \epsilon_o + (RT/2F) \log [UO_2^{\cdot\cdot}][H^{\cdot}]^4/[U^{\cdot\cdot\cdot\cdot}]$, where ϵ_o is 0·419 volt more positive than the normal calomel electrode, or 0·696 volt more positive than the normal hydrogen electrode—*vide supra*, uranous sulphate. The **magnetic susceptibility** of this oxide, $7·51 \times 10^{-6}$, is greater than that of the metal or of any of the higher oxides. S. Freed and C. Kasper studied the subject.

According to J. L. C. Zimmermann, the dioxide, unlike uranium trioxide, has strongly basic properties, readily forming uranous salts with acidic radicles. O. Schmidt studied the adsorption of **argon.** Some of the modes of preparation show that it is not reduced when heated in **hydrogen.** F. W. O. de Coninck found that when the red forms are heated in hydrogen they pass into the black variety with the loss of only a trace of oxygen. C. F. Rammelsberg said that when prepared by the hydrogen reduction process, the dioxide is contaminated with occluded hydrogen. H. von Wartenberg and co-workers found that uranium dioxide cannot be reduced by hydrogen at a press. of about 5 atm. and up to 2500°. E. M. Péligot found that when uranium dioxide is prepared at a low temp. it oxidizes very easily with incandescence when heated in **air,** and that it is pyrophoric, forming the green tritaoctoxide—this was shown by the analyses of J. A. Arfvedson, J. J. Berzelius, R. F. Marchand, E. M. Péligot, J. J. Ebelmen, and E. F. Smith and J. M. Matthews. The varieties prepared at higher temp. do not oxidize so readily. The powdered variety may glow when heated to a high enough temp. and swell up as the tritaoctoxide is formed. This glowing was observed by C. F. Bucholz, J. A. Arfvedson, L. R. Lecanu, and E. D. Clarke; P. Sabatier and J. B. Senderens observed that with a sample they prepared, the oxidation was effected without glowing; and J. Aloy found that a sample prepared at a high temp. was oxidized at a red-heat rather slowly. P. Jolibois and R. Bossuet said that the oxidation of the dioxide in **oxygen** proceeds very rapidly, the action commencing at about 185°. E. D. Clarke found that the oxide burns vigorously with sparking when it is heated in the oxyhydrogen blowpipe flame. H. V. Regnault found that when the oxide is heated to redness in **water** vapour, the tritaoctoxide and hydrogen are formed. According to F. W. O. de Coninck, an 11 vol. soln. of **hydrogen dioxide** slowly converts the dioxide into the monohydrate, which then oxidizes to the trioxide.

E. M. Péligot found that at a red-heat **chlorine** converts the dioxide into uranyl chloride, and that when mixed with carbon, chlorine converts it into uranium tetrachloride—H. E. Roscoe said the pentachloride; H. Hermann found that a mixture of the dioxide and carbon heated in **bromine** vapour furnishes uranium tetrabromide. E. M. Péligot found that **hydrogen chloride** does not attack the red-hot dioxide; and the dioxide does not dissolve in boiling dil. **hydrochloric acid**; but J. Aloy found that a little dioxide is dissolved. A. Colani said that dissolution continues slowly and continuously over a long period of time at a rate varying with the mode of preparation of the oxide; and A. Raynaud, that it requires 3100 grms. of hydrochloric acid of sp. gr. 1·17 to dissolve a gram of the oxide at 17°, and 4650 grms. of **hydrobromic acid** of sp. gr. 1·52 to dissolve the same amount of dioxide. The solubility is a little greater in the boiling acids. L. R. Lecanu observed very little action when the dioxide is heated to redness with **sulphur,** and J. J. Ebelmen said there is no reaction. J. A. Arfvedson found that **hydrogen sulphide** produces no change at a red-heat. F. Bourion found that **sulphur monochloride** converts the dioxide at 230° to 250° into uranium tetrachloride. E. M. Péligot said that boiling dil. **sulphuric acid** has no action on the dioxide, but it dissolves in the conc. acid—O. F. von der Pfordten, H. Rose, and J. J. Ebelmen found that a green soln. of uranous and uranyl sulphates is formed. A. Raynaud found that it requires 2200 grms. of sulphuric acid of sp. gr. 1·79 to dissolve a gram of the dioxide at 17°. The solubility is greater in the boiling acid.

A. Colani added that while only a small amount goes into soln., a considerable amount is converted into insoluble sulphate. O. Schmidt studied the adsorption of **nitrogen,** and of **ammonia.** G. Gore found that the dioxide is slightly attacked by liquid ammonia, and H. Rose, that it is insoluble in a soln. of **ammonium chloride.** According to P. Sabatier and J. B. Senderens, **nitrous oxide** at 450° has no action, but at 500° oxidation occurs ; **nitric oxide** at 500° acts vigorously ; and **nitrogen peroxide** at 500° forms a basic nitrate. F. W. O. de Coninck found that dil. **nitric acid** hydrates the dioxide in the cold, and when warmed the dioxide is dissolved, forming, according to A. Raynaud, uranyl nitrate. It is also soluble in **aqua regia.** A. Raynaud added that the solubility in nitric acid and in aqua regia increases slowly and regularly between 0° and 20°, more rapidly between 20° and 50°, and shows very little change from 50° to 100°. The solubility of the dioxide in acids, in a given time, varies greatly with the previous thermal history of the dioxide. H. C. Greenwood found that when the dioxide is heated with **carbon** in vacuo, a reaction begins at 1490°, and carbon monoxide is formed ; E. Tiede and E. Birnbräuer gave 1600°. O. Heusler found that the equilibrium between uranium dioxide and carbon can be represented by log $p=12 \cdot 09-19100T^{-1}$ between 1480° and 1801°. The heat consumed by the evolution of a mol of carbon monoxide is 87·3 Cals. O. Schmidt studied the adsorption of **carbon monoxide, carbon dioxide, methane, ethane, and ethylene.** A. Michael and A. Murphy observed that when the dioxide is heated at 250° with **carbon tetrachloride** in a sealed tube a little uranium tetrachloride is formed ; and H. Hermann showed that at a red-heat **carbon disulphide** forms $UO_2.2US_2$, but a mixture of carbon dioxide and disulphide vapour has no action. P. Sabatier and A. Mailhe found that **formic acid,** in contact with heated uranium dioxide, is catalytically transformed into carbon dioxide and water. A. Raynaud found that it requires over 12,000 grms. of **acetic acid** to dissolve a gram of the dioxide at 17°. The solubility is rather greater in boiling acid.

P. Plantamour found that **potassium** at the temp. of vaporization does not react with the dioxide. According to E. F. Smith and O. L. Shinn, and J. J. Ebelmen, uranium dioxide resembles molybdenum dioxide in reducing ammoniacal soln. of **silver salts :** $UO_2+2Ag^{\cdot}+2OH'=UO_3+2Ag+H_2O$. F. Isambert also found that hydrated uranium dioxide acts on a neutral soln. of silver nitrate, first precipitating silver oxide : $4AgNO_3+UO_2=2Ag_2O+U(NO_3)_4$; and the green soln. soon turns yellow as the oxide is reduced to silver with the formation of a yellow uranyl salt : $U(NO_3)_4+2Ag_2O=UO_2(NO_3)_2+2AgNO_3+2Ag$.

R. Salvadori found that when a soln. of hydrazine hydrate and uranyl nitrate is boiled for 20 minutes, a green precipitate of **hydrazine uranite,** $(N_2H_5)_2O.7UO_2$. $6H_2O$, is formed. H. Debray fused cupric uranyl phosphate with sodium carbonate, and washed out the sodium phosphate from the cold product ; there remained crystals of **copper tetrauranite,** CuU_4O_7, resembling aventurine. K. A. Hofmann and K. Höschele obtained a deep blue substance approximating **cerium uranite,** $UO_2.2CeO_2$, in cubic crystals by heating a mixture of 5 parts of cerous sulphate and 2 parts of uranyl sulphate with an excess of magnesium chloride in a covered crucible for about 15 hrs. The blue *dihydrate* was obtained by adding ammonia or dil. alkali-lye to a mixed soln. of 30 grms. of uranyl nitrate and 45 grms. of cerous nitrate.

§ 10. Uranium Oxides between the Dioxide and Trioxide

According to E. M. Péligot,[1] by calcining uranium tritaoctoxide, or uranyl nitrate, and rapidly cooling the product, **uranium hemipentoxide**, or simply pentoxide, U_2O_5, is formed. F. Wöhler, and B. Drenckmann obtained it by rapidly heating uranium dioxide in air, and rapidly cooling the product; F. Janda, by heating ammonium diuranate in a graphite crucible; F. W. O. de Coninck, by rapidly heating uranyl sulphate to redness; and F. W. O. de Coninck and M. Camo, by the electrolysis of a soln. of uranyl nitrate—*vide supra*. A. Colani obtained it

as a by-product in preparing uranium tetrachloride. It is sometimes represented as U_4O_5, but this formula is based on the halved at. wt. C. F. Rammelsberg represented it by $UO_2(UO_2)O$, but A. Remelé, and C. F. Rammelsberg regarded its individuality as doubtful. J. J. Ebelmen, A. Colani, and J. L. C. Zimmermann regarded it as a mixture of the dioxide and the tritaoctoxide. C. Stähling found that the green oxide of uranium hydrates slowly on exposure to air, but not so with the black oxide formed by calcination ; and he suggests that the black oxide is uranium hemipentoxide. The hydration explains how the radioactivity of the green oxide but not of the black oxide changes in air. P. Lebeau, and P. Jolibois and R. Bossuet consider that the black oxide is U_3O_8, and that there is no evidence of the formation of an intermediate oxide. A. Colani observed no evidence of its formation in his study of the dissociation press. of uranium tritaoctoxide, $U_3O_8 \rightleftharpoons 3UO_2 + O_2$; but R. Schwarz obtained indications of its existence ; and he added that by igniting the higher oxide in a stream of carbon dioxide in an electric furnace at 1122°, a black residue was obtained corresponding approximately in composition with the formula U_2O_5 ; traces of nitride were produced when nitrogen was employed. The contrary results of J. L. C. Zimmermann were vitiated by his use of a platinum crucible over a gas flame, which permitted reduction. Uranium hemipentoxide is described as a black powder which is stable in air. E. M. Péligot, and F. W. O. de Coninck and M. Camo found that it is transformed into the dioxide when heated in hydrogen ; it dissolves in acids to form a mixed soln. of uranous and uranyl salts. A. Colani added that acetic acid extracts uranium trioxide, and leaves the dioxide ; and the slow evaporation of the soln. in sulphuric acid gives uranyl sulphate.

The calcination of powdered uranium furnishes **uranium tritaoctoxide,** U_3O_8, a compound analyzed by J. J. Berzelius,[2] J. A. Arfvedson, R. F. Marchand, J. J. Ebelmen, E. M. Péligot, etc. C. F. Rammelsberg represented it by the formula $UO_2.2(UO_2)O$; or **uranosic oxide,** $UO_2.2UO_3$. It can be regarded as **uranyl uranate,** $(UO_2)_2UO_4$; or, according to the suggestion of J. L. C. Zimmermann, favoured by P. Groth, as **uranous uranate,** $U(UO_4)_2$, since it contains both quadrivalent and sexavalent uranium atoms :

$$\begin{smallmatrix} O \\ O \end{smallmatrix} \!\!>\!\! U \!\!<\!\! \begin{smallmatrix} O \\ O \end{smallmatrix} \!\!>\!\! U \!\!<\!\! \begin{smallmatrix} O \\ O \end{smallmatrix} \!\!>\!\! U \!\!<\!\!\!< \begin{smallmatrix} O \\ O \end{smallmatrix}$$

The chemical properties are more in accord with the assumption that it is uranosic oxide, $UO_2.2UO_3$, rather than that it is either uranyl uranate, $(UO_2)_2UO_4$, or uranous uranate, $U(UO_4)_2$. The early workers found that this oxide is produced when any of the uranium oxides or hydrated oxides, or any of the uranium salts with a volatile base or acid, is calcined at a red-heat in air—*e.g.* uranyl nitrate, ammonium uranyl carbonate, ammonium uranate, etc. H. Moissan recommended uranyl nitrate ; and W. F. O. de Coninck, uranyl sulphate. A. Colani recommended a temp. exceeding 900° ; H. N. MacCoy and G. C. Ashman, 700°—*vide infra* for the conditions of stability. P. Jolibois and R. Bossuet found that the uranium trioxide passes into uranosic oxide at 502°, and that the action is irreversible ; the only product obtained when the dioxide is heated in oxygen is uranosic oxide. The dissociation press. of uranosic oxide at 900° is approximately the same as the partial press. of the oxygen in air, and E. Friederich and L. Sittig added that it is not advisable to heat the oxide over 1100°, in accord with R. Schwarz's recommendation, but by slowly cooling the oxide in air, any dissociated uranosic oxide may take up oxygen. They therefore recommended preparing uranosic oxide by heating one of the other oxides in oxygen at 900°–1000°. Brown uranium dioxide prepared below 600° began to assume the dark green colour of mixtures of U_3O_8 and UO_2 when warmed to 600°, and it ultimately passes into the green oxide. If kept from the flame gases, uranosic oxide can be prepared below 800°. It is then coloured moss-green ; whereas if prepared over 800° the colour is nearly black— *vide infra,* uranium trioxide. H. V. Regnault obtained uranosic oxide by passing

steam over the red-hot dioxide. The extraction of the oxide from pitchblende has been previously discussed. The commercial oxide is impure. E. Donath recommended preparing the oxide by reducing uranyl acetate to uranium dioxide by heating it in hydrogen, treating the product with nitric acid, and calcining the resulting nitrate; and F. Giolitti and G. Tavanti, by adding 300 c.c. of conc. ammonia to a soln. of 100 grms. of sodium uranyl acetate in 4 litres of water and 50 c.c. of hydrochloric acid, washing the precipitate ten times with a 2 per cent. soln. of ammonium chloride, and then dissolving it in hydrochloric acid. The precipitation with ammonia and the washing are repeated twice, and the product is finally calcined. J. L. C. Zimmermann recommended the following process :

The commercial oxide is dissolved in hydrochloric acid, sat. with hydrogen sulphide, and allowed to stand for a long time. The filtrate from arsenic sulphide, etc., is treated with an excess of ammonia and ammonium carbonate, and ammonium sulphide added to the warm soln. The filtrate is mixed with an excess of hydrochloric acid, and boiled to drive out the dissolved carbon dioxide, and the uranium precipitated as uranyl sulphide by the addition of ammonia and ammonium sulphide. The soln. is warmed on a water-bath to decompose the ammonium sulphide; and the mixture of uranium sulphide and sulphur is well washed with water, and heated over a blast-burner. The resulting uranosic oxide is dissolved in nitric acid, and uranyl nitrate is crystallized from the filtrate. This salt is dissolved in ether, and the filtrate evaporated to dryness on the water-bath, and calcined. The treatment on the resulting uranosic oxide can be repeated once more.

A. N. Pilkoff discussed the subject; and E. Wilke-Dörfurt made the following observations on the preparation of the tritaoctoxide, from cleveite residues used for the extraction of helium. A soln. of the nitrate which had been purified from the rare earth metals and thorium by oxalic acid, and from extraneous heavy metals by hydrogen and ammonium sulphides, yields an oxide, which is not free from alkali. The presence of the latter is attributed to co-precipitation of uranate, and not to adsorption, and can therefore be avoided by the reduction of the uranium. By suitable regulation of the action of ammonium sulphide, it is possible to precipitate uranous instead of uranyl sulphide, and this substance does not show any tendency to retain alkali ; the latter, if absorbed, can be removed by double precipitation, and avoided by working with smaller quantities. The sulphide is readily converted into uranous chloride, which is transformed through the hydroxide into the nitrate ; the latter is oxidized by nitric acid to uranyl nitrate, which is purified by being crystallized from water, and then converted into the oxide, U_3O_8, in which the presence of traces of alkali cannot be detected spectroscopically. The frequently-recommended crystallization of uranyl nitrate from ether is not desirable, since, on the one hand, the product so obtained is not free from alkali, and, on the other, the explosive tendency of the ethereal soln. renders it unsuitable for working with very valuable material. C. L. Parsons obtained the oxide on a large scale.

J. J. Berzelius, and J. A. Arfvedson added ammonia to soln. of uranosic oxide in acids, and obtained a precipitate ranging in colour from dark green to purple-brown. The soln. behaves like a mixture of uranous and uranyl salts; the precipitate, in the absence of definite proof, has been regarded as **hydrated uranosic oxide.** C. F. Rammelsberg treated uranium tetrachloride with ammonia, and obtained a precipitate which takes up oxygen, forming, as he thought, the *hexahydrate*, $U_3O_8.6H_2O$, when dried in vacuo over conc. sulphuric acid. According to J. J. Ebelmen, violet-brown flakes are obtained when a soln. of uranyl oxalate is exposed to sunlight—*vide supra.* J. Aloy obtained a similar product with a 90 per cent. alcoholic soln. of uranyl acetate or an aq. soln. of uranyl acetate mixed with ether ; J. Zehenter obtained a similar product by the action of light on uranyl acetate without the presence of alcohol or ether. J. Aloy and co-workers observed that a soln. of any uranyl salt in the presence of a readily oxidizable organic substance—*e.g.* alcohol, ether, or glucose—when exposed to light or ultra-violet rays yields a violet precipitate containing some of the acid present in the original salt. This acid can be removed by washing with boiling water. The precipitate was considered to be the *dihydrate*, $U_3O_8.2H_2O$. J. Aloy and E. Rodier represented

the violet product of the action of light on uranium salts by $UO_2(OH).O.U(OH)_2$. $O.UO_2(OH)$. A similar product is obtained, without the action of light, whenever uranous and uranic salts are present in neutral or feebly acid soln. at the requisite temp. The evidence of the chemical individuality of these hydrates is not decisive.

Uranosic oxide usually appears as a dark green powder—hence it is sometimes called *green oxide of uranium*. According to A. Remelé, the **colour** depends on its mode of preparation, ranging from black through dark olive-green to green—*vide infra*, uranium trioxide; but, in any case, J. L. C. Zimmermann found that the streak on biscuit porcelain is always green. A. Staehling thought that the black and green oxides are allotropic forms of uranosic oxide—*vide infra*. P. Lebeau found that both have the same ultimate composition, and that the black oxides are stable in air and can be heated at 1000° under atm. press. without decomposition; whilst the green oxides, prepared at temp. below 800°, contain varying amounts of uranium trioxide and can undergo change when exposed to moist air, the uranium trioxide present undergoing hydration. V. M. Goldschmidt and L. Thomassen, and W. Biltz and H. Müller found that the crystal structure deduced from the X-radiogram of uranosic oxide is irregular—*vide infra*, pitchblende. C. J. B. Karsten gave 7·31 for the **specific gravity,** and J. J. Ebelmen, 7·31. W. F. Hillebrand gave for the sp. gr. at 19·1° to 30·3°/4°, and the **molecular volumes** of the oxides UO_n:

n	2·417	2·201	2·051	2·022	2·005
Sp. gr.	10·15	10·98	10·83	10·82	10·95
Mol. vol.	27·28	24·90	25·02	25·01	24·69

The results of W. Biltz and H. Müller are indicated below in connection with uranium trioxide; and similarly also with the **volatilization** of uranosic oxide. M. L. Phillips studied the radiation of light from uranium oxide. E. Donath obtained 0·07979 for the **specific heat** near ordinary temp.; and A. S. Russell 0·0616 between 0° and —77°, and 0·0428 between —77° and —190°; or 0·0429 at —134°, 0·0616 at —39°, and 0·0710 at 22°, with the corresponding values for the **molecular heat** 36·15, 51·96, and 59·85 respectively. E. M. Péligot observed a loss of 0·7 to 1·0 per cent. of oxygen when uranosic oxide is vigorously calcined, and it passes into the pentoxide; but C. F. Rammelsberg found that it is stable at temp. high enough to enable uranium to be quantitatively determined in this form. P. Jolibois and R. Bossuet found that with 3 hrs.' heating in vacuo, at 1000°, uranosic oxide only lost a very small fraction of its oxygen. J. L. C. Zimmermann said that uranosic oxide is stable at a red-heat only in oxygen gas; a little oxide is lost if it be heated in air to redness and rapidly cooled; and W. F. Hillebrand showed that if it is heated under molten borax, uranium dioxide is formed. J. L. C. Zimmermann observed that the reaction $U_3O_8 \rightleftharpoons 3UO_2 + O_2$ is reversible, and that equilibrium is very slowly attained. A. Colani found that the **dissociation pressure** p mm. is:

	625°	745°	850°	940°	990°	1055°	1125°	1165°
p	15	29	108	157	208	248	281	315

and by extrapolation, $p=760$ mm. between 1400° and 1500°. This shows how the higher oxide passes into the dioxide when heated in an inert gas, or in the presence of fused borax. C. Zengelis observed a discoloration on silver suspended over a layer of the oxide in a closed vessel, indicating a slight vaporization at ordinary temp. P. Jolibois and R. Bossuet found that uranous oxide lost only a very small fraction of oxygen when heated for 3 hrs. at 1000° in vacuo; and to convert the tritaoctoxide completely into the dioxide required a temp. of 2000° in vacuo. W. Biltz and H. Müller represented the effect of heat at different temp. and press. on uranosic oxide by curves resembling Fig. 5. Uranium trioxide (*q.v.*) is not formed. Observations were also made by G. F. Hüttig, and C. Wagner and W. Schottky. C. Staehling discussed the radioactivity of the uranium oxides—**4. 26, 11**; and A. L. Helfgott, the radiation. W. G. Mixter gave for the **heat of formation**

$3U+4O_2=U_3O_8+845\cdot2$ Cals. ; and for the heat of formation from uranium dioxide 78 Cals.—W. Biltz and H. Müller calculated 117 Cals. from the equilibrium constant of the reaction : $U_3O_8+2H_2=2H_2O+3UO_2$. C. Staehling observed that the freshly-calcined oxides lost from 1 to $30\cdot7$ per cent. of their radioactivity when kept for about five years, and half the activity was lost during the first six months. The loss was greatest with the green oxide and least with the black oxide. If the oxide be converted into nitrate, and calcined for uranosic oxide the original activity is restored, but it immediately commences to diminish as before. The activity can be restored by simple calcination. During the process of restoration, the oxide undergoes loss in weight, due, for the most part, to the removal of moisture. The black oxide which shows little loss in activity also shows little loss in weight or alteration in activity on calcination. The green oxide on exposure to the air in thin layers undergoes hydration as well as a loss in activity, the hydration presumably diminishing the superficial density of the uranium atoms. The black oxides obtained by calcination at high temp. do not hydrate and show little or no decrease in radioactivity. These are supposed to show that the black oxide is probably an allotropic modification of the green oxide. A. Dorabialska, and

FIG. 5.—Action of Heat on Uranosic Oxide.

E. Wiegand studied the radiation of heat from the oxide. J. O. Perrine observed no **fluorescence** with ultra-violet light; M. L. Phillips, the radiation from the oxide; and E. L. Nichols and D. T. Wilber, no flame phosphorescence. W. P. Jorissen and W. E. Ringer found that 100 mgrms. of uranosic oxide, after an hour's exposure to **cathode rays** and cooling, weighed $71\cdot2$ mgrms. The radioactivity was also increased about 30 per cent. H. N. MacCoy and G. C. Ashman recommended thin films of uranosic oxide as a standard for a-ray activity. The radioactivity was studied by W. P. Widdowson and A. S. Russell, B. B. Boltwood, etc.—*vide* 4. 26, 2. F. Behounek observed no increase in the **radioactivity** of uranosic oxide by exposure to sunlight. The subject was studied by S. Maracineanu. D. K. Goralevitsch recommended U_3O_8 as a standard for radioactivity. The subject was studied by A. B. Verigo. G. Kirsch and H. Pettersson studied the reflection of a-particles. J. Vrede studied uranosic oxide as a detector of electromagnetic waves. According to F. Streintz, the **electrical conductivity** of the compressed powder is negligibly small. E. Friederich and L. Sittig compressed the powder into rods, heated them in oxygen at $1000°$, and found the sp. resistance to be 42×10^6 to 45×10^6 ohms per sq. mm. at ordinary temp., and about one-tenth this value at $300°$. M. le Blanc and H. Sachse gave for the sp. conductivity, K :

20°	50°	100°	150°	200°	300°	400°	500°
K 10^{-7}	$2\cdot5\times10^{-7}$	$9\cdot0\times10^{-7}$	$3\cdot0\times10^{-6}$	$1\cdot5\times10^{-5}$	$1\cdot3\times10^{-4}$	$7\cdot0\times10^{-4}$	$2\cdot4\times10^{-3}$

C. A. Pierlé found that the **electrode potential** of uranosic oxide, against a soln. of $14\cdot3$ grms. of uranyl nitrate per litre, is $0\cdot776$ volt, the same as that of uranous oxide. L. Andrieux found that the electrolysis of a soln. of uranosic oxide in fused magnesium, calcium, or lithium pyroborate and fluoride yields uranium boride, UB^4. Uranosic oxide is paramagnetic; and K. Honda gave for the **magnetic susceptibility** $4\cdot34\times10^{-6}$, while E. Wedekind and C. Horst gave $0\cdot95\times10^{-6}$.

J. A. Arfvedson, and P. Jolibois and R. Bossuet said that the only product obtained by heating uranosic oxide in **hydrogen** is uranium dioxide; and P. Jolibois and R. Bossuet found that the action commences at $625°$, and the reduction can be completed at $650°$. W. Biltz and H. Müller represented the equilibrium condition $K=p_{H_2O}/p_{H_2}$, in the reaction : $U_3O_8+2H_2\rightleftharpoons2H_2O+3UO_2$, by $14\cdot5$ at $545°$. E. Newbery and J. N. Pring observed that at about $2000°$, in contact

with hydrogen at 150 atm. press., uranium tritaoctoxide is reduced to the dioxide. According to P. Jolibois and R. Bossuet, uranosic oxide is not oxidized to the trioxide when heated in **oxygen,** so that the reaction $6UO_3=2U_3O_8+O_2$ which occurs at 502° is not reversible—*vide infra,* uranium trioxide. Uranosic oxide is insoluble in **water.** J. A. Arfvedson stated that uranosic oxide which has been heated to redness dissolves very slowly and sparingly in dil. **hydrochloric acid,** and H. Rose added that when it is digested with hydrochloric acid, uranium trioxide is mainly extracted. G. J. Fowler and J. Grant found that when uranosic oxide is heated with **potassium chlorate,** oxygen comes off at 390°, chlorine is also evolved, and potassium uranate is formed. J. J. Ebelmen said that **sulphur** at a red-heat reduces uranosic oxide to uranium dioxide. F. Bourion found that **sulphur mono-chloride** and uranosic oxide in a sealed tube at 230° to 250° form uranium tetra-chloride. J. A. Arfvedson found that the oxide which has been heated to redness dissolves slowly and sparingly in dil. **sulphuric acid,** but it dissolves more readily, and completely in boiling conc. sulphuric acid. F. Isambert observed that uranosic oxide dissolves in nitric acid to form uranyl nitrate. According to O. F. von der Pfordten, uranosic oxide does not exist in acid soln., but rather as a mixture of the uranous and uranyl salts. C. F. Bucholz found that uranosic oxide is reduced to uranium dioxide by **carbon** at a red-heat. R. Schwarz said that when the oxide is heated in a current of **carbon dioxide** at 1120°, it yields the hemipentoxide. H. Hermann found the dioxide is obtained with a mixture of the vapour of **carbon disulphide** and carbon dioxide—and with carbon disulphide alone $UO_2.2US_2$ is formed. A. Michael and A. Murphy found that uranium pentachloride is formed when uranosic oxide is heated for many hrs. with **carbon tetrachloride** in a sealed tube at 250°. H. C. Bolton said that **citric acid** in the presence of potassium nitrate dissolves powdered pitchblende. F. W. O. de Coninck said that the reaction which occurs when uranosic oxide is heated with **calcium oxalate** can be represented : $2CaC_2O_4+U_3O_8=2CaCO_3+2CO_2+3UO_2$—*vide supra,* uranium dioxide. P. Sabatier and A. Mailhe studied its action as a catalyst in reducing **ethyl alcohol** to ethylene. According to J. L. Gay Lussac and L. J. Thénard, **potassium** or **sodium** at a red-heat reduces uranosic oxide to the dioxide. J. Aloy, and E. K. Rideal obtained a similar product by heating uranosic oxide with **magnesium.** D. Balareff found that **barium oxide** reacts vigorously with uranium tritaoctoxide below 300° with the evolution of much heat. A. Ditte observed that the **alkali fluorides** and **thallous fluoride** form yellow, crystalline plates of a complex salt. F. Isambert found that uranosic oxide very slowly separates silver from a soln. of **silver nitrate.**

C. A. Pierlé found that the black deposit formed when uranium salts are electrolyzed is not $U_3O_8.2H_2O$, as stated by E. F. Smith, but rather a dihydrated *uranium tritadecoxide,* $U_3O_{10}.2H_2O$, and its potential against a soln. of 14 grms. of uranyl nitrate per litre is -0.6872 volt, whereas with uranosic oxide the potential is -0.776 volt. According to J. L. C. Zimmermann, an impure hydrated form of *uranium heptitacosioxide,* U_7O_{20}, or $UO_2.6UO_3$, or $U_3O_8.4UO_3$, is produced by allowing uranyl sulphide to stand under a soln. of ammonium sulphide for a couple of months in the absence of air. The chocolate-brown precipitate is washed with air-free water, dried at 100°, extracted with carbon disulphide to remove the sulphur, and dried at 100°. It contains traces of probably uranyl sulphide, and of an ammonium salt. The black powder is soluble in mineral acids, with the evolution of a small amount of hydrogen sulphide and the formation of a yellowish-green soln. It is not affected by a soln. of ammonium sulphide ; it is partly soluble in a soln. of ammonium carbonate ; it is not affected by alkali-lye ; and potassium permanganate is decolorized by its soln. in sulphuric acid. When heated in a tube, water and a little ammonia are given off, at 270° the colour becomes brick-red, and at a high temp. greenish-black.
Reference was made to **pitchblende, or uraninite,** in connection with the history of uranium ; and, in allusion to the radioactive elements which it contains, it has been said that " pitchblende is a perfect museum of chemical rarities." It occurs as a mineral in Bohemia, Saxony, Hungary, Cornwall, Norway, Turkey, United States, Bengal, East Africa, Quebec, etc. It usually occurs massive, botryoidal, granular, or with a columnar or curved lamellar structure. Crystalline forms are

rare. It may be coloured black and resemble pitch—hence the name pitchblende—or it may have a grey, green, or brown tinge. The streak is brownish-black, grey, or olive-green. F. von Kobell[3] applied the term *nasturan*—from ναστός, dense—to a compact variety which was virtually free from thoria and the rare earths. Of the crystalline varieties, there are : *uranniobite* of R. Hermann which comes from Norway, occurring in octahedral crystals of sp. gr. 9·0 to 9·7 ; **bröggerite** of C. W. Blomstrand—named after W. C. Brögger—which comes from Anneröd, Norway, where it occurs in octahedral crystals. Analyses of bröggerite were given by W. Riss, G. Tschernik, W. Elsholz, G. Kirsch, W. F. Hillebrand, C. W. Blomstrand, and K. A. Hofmann and W. Heidepriem. The sp. gr. given by the same observers ranges from 5·96 to 11·59—average 8·73. C. W. Blomstrand gave $6U^{IV}R^{II}(U^{VI}O_6)$. $U_3^{IV}(U^{VI}O_6)_2$; and W. E. Hidden, $3RO.UO_3$. The **cleveite** of A. E. Nordenskjöld—named after P. T. Cleve—comes from Arendal, Norway, where it occurs in cubic (dodecahedral and octahedral) crystals of sp. gr. 7·50. It was analyzed by A. E. Nordenskjöld, W. E. Hidden and J. B. Mackintosh, and W. Elsholz. The formula approximates $6RO.2UO_3.3H_2O$. The crystals were described by F. Müllbauer, and A. E. Nordenskjöld ; and occluded gases by M. W. Travers, W. Ramsay, and H. Deslandres. The *nivenite* of W. E. Hidden and J. B. Mackintosh—named after W. Niven—occurs in Llano Co., Texas, in velvety black masses with an indistinct crystallization, of sp. gr. 8·01 and hardness 5·5. Nivenite is more quickly attacked by sulphuric acid than other varieties.

Analyses were reported by the early workers M. H. Klaproth, C. F. Rammelsberg, J. J. Ebelmen, R. Hermann, C. H. Pfaff, A. Becker and P. Jannasch, W. Steinkuhler, C. W. Knight, H. Hirschi, T. L. Walker, F. Hecht and E. Körner, C. von Hauer, J. D. Whitney, F. A. Genth, W. R. Criper, P. Krusch, W. Elsholz, K. Nenadkevich, C. B. Comstock, and T. Scheerer ; and more recent analyses by J. Lorenzen, P. K. Grigoreff, W. E. Hidden and J. B. Mackintosh, C. W. Davis, W. Marckwald, J. Step, A. Schoep, P. Schei, Y. Brière, T. H. Laby, G. Kirsch, G. P. Tschernik, K. A. Hofmann and W. Heidepriem, H. V. Ellsworth, J. S. de Lury and H. V. Ellsworth, R. C. Wells, A. E. Nordenskjöld, F. W. Clarke, and W. F. Hillebrand. The proportion of UO_3 ranges from 14·00 to 59·3 per cent. ; UO_2, 19·89 to 70·99 ; ThO_2, 1·65 to 9·79 ; rare earths—$CeO_2.La_2O_3$, and Y_2O_3—up to 12·67 per cent. ; PbO_2, 3·07 to 11·31 ; CaO, 0·08 to 1·04 ; MgO, up to 0·30 ; ZnO, up to 0·44 ; MnO, up to 0·09 ; Na_2O, up to 0·31 ; H_2O, 0·43 to 4·28 ; Fe_2O_3, 0·09 to 1·26 ; Cb_2O_5, up to 0·96 ; ZrO_2, up to 0·2 ; SiO_2, up to 0·90 ; Al_2O_3, up to 0·20 ; P_2O_5, up to 0·22 ; As_2O_5, up to 2·34 ; Bi_2O_3, up to 0·75 ; SO_3, up to 0·19 ; F, up to 0·04 ; as well as up to 2·63 per cent. of nitrogen (helium). The helium was discussed by W. Ramsay and co-workers, J. N. Lockyer, W. A. Tilden, N. A. Langlet, etc. ; the zirconium and hafnium content, by O. Free ; the thallium contents, by S. Wleugel ; and the polonium and radium contents and the radioactivity, as well as the lead contents, by M. and P. Curie and G. Bémont, A. Debierne, G. F. Barker, R. C. Wells, B. B. Boltwood, T. L. Walker, G. Bardet, O. Mügge, V. M. Goldschmidt, F. Kolbeck and P. Ulrich, G. Kirsch, H. V. Ellsworth, A. Becker and P. Jannasch, C. W. Davis, F. Giesel, O. Behrendsen, etc.—*vide* **4**. 26, 3. The radioactivity and age of the mineral was discussed by A. E. Fersman—*vide* **4**. 26, 3. R. J. Moss discussed the helium content. J. K. Marsh estimated the rare earth content of uraninites.

G. Kirsch suggested that there are two distinct minerals—one an oxide, UO_2, and the other a uranate, U_2O_5 or U_3O_8, which are represented by radioactive transformation pseudomorphs. The cubic oxide is called *ulrichite*—after C. Ulrich —while bröggerite and cleveite are regarded as altered varieties containing thoria or the rare earths. Its sp. gr. is 7·5 and hardness 6. Massive pitchblende is cryptocrystalline and probably rhombic. B. Szilard said that just as thorianite contains 65 to 74 per cent. of thorium and 4 to 11 per cent. of uranium, so uraninite contains 65 to 74 per cent. of uranium, and 4 to 11 per cent. of thorium ; and just as thorium hydroxide dissolves in a soln. of thorium nitrate, so does uranium hydroxide dissolve in a soln. of thorium nitrate ; in the former case, on evaporation,

a substance similar in composition to thorianite is obtained, whilst in the latter a yellow substance similar to uraninite is formed. Salts of thorium and uranium dissolve not only the hydroxides named above, but also the hydroxides of the rare earth metals and of nearly all those metals occurring in thorianite and uraninite ; the compounds obtained with yttrium, iron, lead, and zirconium have characteristic properties. All are amorphous. B. Szilard suggested that thorianite and uraninite are formed in nature by processes analogous to that just described. C. W. Blomstrand said that the natural uranates may be taken as a type built up in accord with the formula $3RO.UO_3$, in which the uranium trioxide uniformly appears as an ortho-acid, while the basic portion of the molecule is composed principally of uranous oxide, a portion of which is replaced by lead or some kindred metal. C. W. Blomstrand regarded uraninite as a derivative of sexibasic orthouranic acid, $U(OH)_6$, in which hydrogen is replaced by quadrivalent uranium :

$$U \underset{O}{\overset{O}{\lessgtr}} \underset{O}{\overset{O}{\gtrless}} U \underset{O}{\overset{O}{\lessgtr}} U \underset{O}{\overset{O}{\gtrless}} U \underset{O}{\overset{O}{\lessgtr}} \underset{O}{\overset{O}{\gtrless}} U$$

True pitchblende or uraninite is considered to be represented best by the formula $7UO_2.PbO.5UO_2$, i.e. $U_7Pb(UO_5)_5$, or by $UPbUO_6.2U_3(UO_6)_3$. There are two forms of the thorouraninites—(i) bröggerite, $UO_2.RO.UO_3$, i.e. $URUO_6$, or $6URUO_6.U_3(UO_6)_2$; and (ii) cleveite, $UO_2.4RO.2UO_3.4H_2O$, or $UR_4(UO_6)_2.4H_2O$. W. F. Hillebrand, however, showed that the generalized or idealized formula, $U_3^{IV}(U^{VI}O_6)_2$, or $(UO_2)_3(UO_3)_2$, of C. W. Blomstrand is not of general application. A. Schoep found that the uraninite of Katanga, Belgian Congo, has the formula $(UO_2)_3(UO_3)_2$, and he suggested that originally uraninite was uranium dioxide, and thorianite, thorium dioxide—both minerals being isomorphous and analogous in composition. The trioxide, UO_3, found with uraninite is an oxidation product of the original dioxide, UO_2. The hypothesis was supported by W. Biltz and H. Müller. The irreversibility of the reaction : $U_3O_8+O=3UO_3$ under certain conditions does not invalidate this argument—vide infra, uranium trioxide. The alteration and weathering of uraninite was discussed by A. L. Hacquaert, and H. V. Ellsworth.

The crystals of uraninite are usually octahedra or dodecahedra, but rarely cubes. H. S. Spence, R. van Aubel, and R. Brauns described the crystals. According to V. M. Goldschmidt and L. Thomassen, the X-radiograms of pitchblende, bröggerite, cleveite, and thorianite correspond with a regular, face-centred lattice, the edges being 5·56 A. for thorianite, 5·47 A. for bröggerite, and 5·47 A. for cleveite. They correspond with isomorphous mixtures of the three oxides and also of lead dioxide. The crystalline substance in thorianite and bröggerite has a uniform arrangement, with a distortion of the single points, as if the crystal were composed of sub-parallel planes. The subject was studied by A. Hadding and R. van Aubel. Cleveite yields uranosic oxide on ignition. Bröggerite, after ignition, shows the uranous oxide structure.

The crystal substance in pitchblende is present in a finely divided state (10^{-4} to 10^{-7} cm.). The uranium atoms form face-centred cubes with edges 5·42 A. to 5·45 A. It is supposed that, as the ground lattice of these minerals is uranous oxide, the excess of oxygen corresponding with uranic oxide is present in solid soln. This case is analogous to the occurrence of yttrium fluoride in calcium fluoride. W. Biltz and H. Müller made some observations on this subject. The sp. gr. of the analyzed amorphous specimens range from 6·40 to 9·73 ; the crystalline varieties from about 9·0 to 9·7. J. J. Saslawsky studied the mol. vol. ; and W. Steinkuhler, and H. Schneiderhöhn, the hardness, which is about 5·5. R. Cusack gave 1188° for the m.p. This was corrected by A. L. Fletcher to 1238°, who also observed specimens softening at 1220°, flowing slowly at 1265° to 1330°, and rapidly at 1380° to 1440°. W. C. Brögger said that the ratio of the axes of the heat

conductivity curve is $1 : 1 \cdot 00389$, corresponding with cubic crystallization.
J. Verhaeghe studied the arc spectrum; and A. de Gramont, the spark spectrum.
E. Wartmann said that the mineral is slightly conducting; and F. Beijerinck,
and R. D. Harvey, that it is a non-conductor; and E. T. Wherry added that
the crystals make a poor radio-detector. The mineral is not attracted by a magnet,
but F. von Kobell said that it is attracted after it has been calcined. Pitchblende
is not easily attacked by hydrochloric acid, but it forms a yellow soln. with nitric
acid. It is also soluble in sulphuric acid.

Some complex carbonates (q.v.) are alteration products of uraninite. The *Uranokker*
of A. G. Werner,[4] the *lichtes Uranpecherz* of J. K. Freiesleben, the *uranisches Gummierz*
and the *Urangummi* of A. Breithaupt, the *Phosphorgummite* of R. Hermann, and the
gummite of J. D. Dana are alteration products of uraninite of very variable composition.
A. L. Hacquaert discussed pseudomorphs of gummite and uranophane after uraninite.
These minerals contain, according to the analyses of C. M. Kersten, F. Ragsky, R. Hermann,
H. von Foullon, F. A. Genth, and H. Buttgenbach, 61·33 to 75·20 per cent. UO_3; 2·51 to
5·57, PbO; 0·36 to 8·64, Fe_2O_3; 0·05 to 1·92, Mn_2O_3; 2·05 to 6·00, CaO; 0·09 to 2·20,
MgO; up to 1·08, BaO; 4·26 to 5·13, SiO_2; and 9·41 to 11·86, H_2O. The *uranisches
Pittinerz* of A. Breithaupt, or the *pittinite* of R. Hermann, is a variety of gummite; as are
also the *eliasite* of R. Hermann; the *yttrogummite* of A. E. Nordenskjöld; the *thoro-
gummite* of W. E. Hidden and J. B. Mackintosh; the *chlorothorite* of W. E. Hidden; the
coracite of J. L. le Conte, J. D. Whitney, and F. A. Genth; and the *soddite*, $12UO_3.5SiO_2.$
$14H_2O$—named after F. Soddy—and *chinkolobwite*, $12UO_3.5SiO_2.14H_2O$—named from the
locality, *Chinkolobwe*—from Katanga, Belgian Congo, described by A. Schoep. Soddite
occurs in dull yellow, rhombic prisms, with the axial ratios $a : b : c = 0 \cdot 7959 : 1 : 1 \cdot 6685$.
The refractive indices are $\beta = 1 \cdot 64$ and $\gamma = 1 \cdot 68$. V. Billiet gave $a = 1 \cdot 645$, and $\beta = 1 \cdot 662$.
According to A. Schoep, the sp. gr. is 4·627, and the hardness is 4. Chinkolobwite occurred
as a felted mass of canary-yellow needles on a specimen of soddite, and the rectangular
prismatic crystals have the refractive indices $\beta = 1 \cdot 635$, and $\gamma = 1 \cdot 646$, with a negative
optical character. There is also **sklodowskite**—named after Mme. Curie-Sklodowska—
a hydrated magnesium uranium silicate, $MgO.2UO_3.2SiO_2.7H_2O$. It occurs in pale yellow,
rhombic prisms, which have the axial ratios $a : b : c = 0 \cdot 3114 : 1 : 1 \cdot 0554$; the (100)-cleavage
is perfect. V. Billiet gave for the indices of refraction $a = 1 \cdot 613$, $\beta = 1 \cdot 635$, and $\gamma = 1 \cdot 657$.
A. Schoep found that the sp. gr. is 3·54; the optical character is negative; and the pleo-
chroism, colourless to yellow. N. A. Yajnik and S. J. Kohli studied the radioactivity of
uranium ochre.

§ 11. Uranium Trioxide and its Hydrates

J. J. Ebelmen [1] prepared **uranium trioxide**, or **uranic oxide**, UO_3, by heating uranyl hydroxide to 300°—the product appears from the analysis to contain some uranosic oxide. He also obtained it by raising the temp. of ammonium uranyl carbonate very gradually to 300°, and holding it there for a long time; and O. Brunck said that this salt is best heated at a temp. not exceeding 300°, and in a current of air, until the exit gases no longer turn red litmus blue. The product contains traces of ammonia. H. Lienau heated about 50 grms. of ammonium uranate in a flask, on an oil-bath at 250°, for 30 hrs.; F. W. O. de Coninck heated uranyl sulphate to dull redness and obtained the trioxide; and E. M. Péligot, and F. W. O. de Coninck heated uranyl nitrate at 250° until no acid vapours are given off. P. Lebeau, V. A. Jacquelain, R. de Forcrand, and O. Brunck showed that the trioxide prepared from the nitrate is always contaminated with basic nitrate, even when heated for a long time at 350°. P. Lebeau said that the product

can be obtained free from nitrate if the oxide obtained at a low temp. be heated in oxygen gas for a long time at 500°—but the trioxide then contains traces of uranosic oxide. G. F. Hüttig and E. von Schröder, and W. Biltz and H. Müller prepared hydrated uranium peroxide by treating a soln. of 20 grms. of uranyl nitrate in 200 c.c. of water with 3 to 10 per cent. hydrogen dioxide, washing, and drying the precipitate at 60° to 70°. The sulphur-yellow powder was heated in an atm. of oxygen in an electric furnace at 350° for 3 to 4 hrs., and then from 30 to 60 min. at 400°. The product was cooled in a desiccator. The colour of the oxide is orange.

Analyses by W. Biltz and H. Müller correspond with UO_3; the observed ratio $U : O$ ranges from $1 : 2.97$ to $1 : 3.07$. If the at. wt. of uranium is taken to be 120, the formula is U_2O_3. According to E. M. Péligot, and C. F. Rammelsberg, the formula is $(UO_2)O$, where the bivalent radicle UO_3 is called *uranyl*, and accordingly uranium trioxide can be regarded as *uranyl oxide*, $(UO_2)O$. This is supported by the difficulty in preparing the hexahalides—uranium sexavalent—and the ease with which the uranyl salts—$UO_2(NO_3)_2$, UO_2SO_4, UO_2Cl_2, UO_2F_2, etc.—can be prepared. Uranium trioxide is an orange-yellow powder; J. J. Ebelmen said brick-red. According to F. W. O. de Coninck, when crystalline uranium nitrate is rapidly calcined, it yields a red modification of the trioxide, which is supposed to be a polymeride, $(UO_3)_2$, of the orange variety. The orange variety is formed by the slow thermal decomposition of the nitrate and it is partially transformed into the red variety if kept at a red-heat for some time. If the red form is kept for 40 hrs. at a dull red-heat, or at a high temp., it is converted into a brown oxide, but it does not give the green uranosic oxide· if heated to redness in a closed platinum crucible. R. de Forcrand also prepared what he regarded as a polymeride of the trioxide by heating uranyl nitrate at 500° to 600°. Attempts to determine the mol. wts. have not been successful. So far as the available evidence is concerned the difference in colour may represent nothing more than a difference in the grain-size of the two products. V. M. Goldschmidt and L. Thomassen, and W. Biltz and H. Müller examined X-radiograms of uranium trioxide, and found it to be amorphous—*vide infra*. W. Biltz, and W. Biltz and H. Müller measured the **specific gravity** and **molecular volume** of the oxides, at 25°/4°, between $UO_{3.069}$ and $UO_{1.992}$, and calculated the mol. vol. of the contained oxygen. The results are plotted in Fig. 6. The following is a selection from the results, for UO_n:

FIG. 6.—Molecular Volumes of the Uranium Oxides.

FIG. 7.—The Thermal Decomposition of Uranium Trioxide.

n	3.069	2.920	2.666	2.537	2.454	2.333	2.262	2.000	1.992
Sp. gr.	6.039	7.074	8.301	8.776	9.384	9.756	10.90	10.75	10.80
Mol. vol.	47.57	40.28	33.83	33.44	29.58	28.24	25.17	25.21	25.03
Vol. O	11.4	9.45	7.9	7.9	6.95	6.65	5.5	6.3	6.2
G. Beck gave 7.29 for the sp. gr., and 39.2 for the mol. vol. D. Balareff discussed the mol. vol. L. Elsner stated that when uranium oxide is heated in a porcelain oven, there is evidence of some **volatilization**; and W. Biltz and H. Müller observed that in a quartz bulb $UO_{2.61}$ gave a faint sublimate at 1214° and 1.0 mm. press.; $UO_{2.46}$, a faint sublimate at 1240° and 1.4 mm.; $UO_{2.30}$, a very faint one at 1160° and 0.3 mm.; and $UO_{2.20}$, a faint one at 1240° and 0.02 mm. In another set of experiments at 1300°±20°, over about 10 hrs., and about 1 mm. press., 0.036 per cent. sublimed from $UO_{2.000}$; 0.6 per cent. from $UO_{2.3}$; and 4.0 per cent. from $UO_{2.667}$. The sublimate approximated $UO_{2.15}$. The evolution of oxygen from the solid thus favoured sublimation—the residue from the UO_2 remained unchanged, the other left a residue approximating $UO_{2.17}$. J. J. Ebelmen, and

F. W. O. de Coninck discussed the decomposition of uranium trioxide : $6UO_3$ $=2U_3O_8+O_2$. According to O. Brunck, the oxygen which is evolved contains a perceptible quantity of ozone. At a constant press. of 10 mm. of oxygen, W. Biltz and H. Müller obtained the results indicated in Fig. 7, and they noted that the colour of UO_3 is pale orange-yellow, and as it passes into $UO_{2.9}$, the colour becomes greyish-brown with a greenish tinge, and the X-radiogram shows the presence of U_3O_8 on passing to $UO_{2.8}$, the green tinge becomes more marked, until with $UO_{2.67}$ the colour is moss-green or olive-green ; on attaining $UO_{2.6}$, the colour darkens, and becomes almost black with $UO_{2.2}$, and the X-radiogram shows the presence of U_3O_8, as well as of UO_2 ; on passing to $UO_{2.1}$ and UO_2, the colour becomes black or dark brown, and the X-radiogram of UO_2 alone appears. W. Biltz and H. Müller measured the **dissociation pressure** of the oxides between UO_3 and U_3O_8. The results are illustrated by Fig. 8. The observed dissociation press. are not equilibrium press., although in some cases they may approach that state. A. Fischer and co-workers observed the decomposition of uranium trioxide in air between 470° and 580° to form uranosic oxide ; and P. Jolibois and R. Bossuet
FIG. 8.—Dissociation Pressure of Uranium Oxides.

observed breaks at 360° when the trioxide is heated at 30° and at 710 mm. press. ; D. Balareff observed that in vacuo, at 502°, the formation of uranosic oxide is rapid, and the change from uranosic oxide to the trioxide is irreversible. P. Lebeau observed that a preparation of uranosic oxide kept for about five years acquires a brownish-green surface film of hydrated trioxide ; and that the greyish-black uranosic oxide obtained by heating the oxalate at 350° becomes brownish-orange and increases in weight when heated for 12 hrs. in air at 350° ; if the uranosic oxide has been heated to 800°, it is inactive and is dead-burned. W. Biltz and H. Müller made analogous experiments which showed that finely-divided uranosic oxide can be oxidized, and that the oxidation of uranosic oxide to the trioxide in geological processes is rendered probable.

W. G. Mixter found that the **heat of formation,** (U,3O)=303·9 Cals. ; (UO_2,O)=34·2 Cals. ; and U_3O_8+O=$3UO_3$+16·2 Cals. R. de Forcrand gave 19·803 Cals. for the heat of soln. of the trioxide in dil. nitric acid. A. Wehnelt classed uranium as an " inactive oxide " as far as the **emission of electrons** is concerned when it is fixed on a platinum disc and used as the cathode of a discharge tube. M. L. Phillips studied the radiations from the incandescent oxide. F. Behounek observed no increase in the radioactivity of the trioxide on exposure to sunlight ; the subject was studied by S. Maracineanu. M. le Blanc and H. Sachse found the sp. **electrical conductivity** of the trioxide to be over 5×10^{-8} at 400°. According to E. Wedekind and C. Horst, the trioxide is paramagnetic, and the **magnetic susceptibility** 1.08×10^{-6} unit. The subject was discussed by W. Biltz and C. Fendius, who observed 293 Cals. for the heat of formation.

V. Kohlschütter and K. Vogdt attributed the retention of gases like **helium, nitrogen,** and **nitrous oxide** to the water present in the oxide. The subject was discussed by C. Friedheim—*vide infra*, hydroxylamine uranate. P. Sabatier and J. B. Senderens, and H. Hermann observed that when heated in **hydrogen,** it is reduced to a lower oxide. G. Gore found that dry **hydrogen chloride** forms a yellow product soluble in water ; F. O. von der Pfordten, that **acids** form yellow soln. Conc. **hydrobromic acid** was found by R. Sendtner to dissolve hydrated uranium trioxide, forming a soln. of uranyl bromide ; but **hydriodic acid** acts as a reducing agent. A. W. Cronander found that when the trioxide is heated in a sealed tube with **phosphorus pentachloride,** the complex $PCl_5.UCl_5$ is formed—*vide infra*. V. Kohlschütter found that **hydrogen sulphide** reduces neutral, alkaline, or feebly acidic soln. R. Sendtner found that hydrated uranium trioxide dissolves in dil. **selenic acid**, forming a soln. of uranyl selenate ; and in **selenious acid**, forming a soln.

of uranyl selenite. H. Moissan found that when uranium trioxide mixed with **carbon** is heated in the electric furnace at 3000°, it is reduced to the metal ; O. Brunck, that it is reduced to uranosic oxide when heated in **carbon dioxide** ; H. Hermann, that **carbon disulphide** vapour mixed with carbon dioxide reduced it to the dioxide ; and H. E. Quantin, that **carbon tetrachloride,** or a mixture of chlorine and carbon monoxide, at a high temp., forms a mixture of uranyl dichloride and uranium hexachloride ; but A. Michael and A. Murphy said that in a sealed tube at 250°, carbon tetrachloride and uranium dioxide form uranium pentachloride, and P. Camboulives, that carbon tetrachloride at 360° forms the tetra- and penta-chlorides. L. Kahlenberg and H. W. Hillyer found that the trioxide is insoluble in a boiling, aq. soln. of **potassium tartrate ;** and W. Gibbons, that it is soluble in **oleic acid.** G. Rauter found that when heated with **silicon tetrachloride** in a sealed tube, the trioxide forms chlorine, uranium tetrachloride, uranyl chloride, and silica.

T. Graham prepared a **colloidal solution** of hydrated uranium trioxide by adding alkali-lye to a soln. of uranyl nitrate or chloride in the presence of sugar ; the salts and alkali were removed from the deep orange soln. by dialysis. The soln. was fairly stable, and it was coagulated by electrolytes. B. Szilard obtained the colloidal soln., containing a little electrolyte, by the gradual addition of uranyl hydroxide to a dil. soln. of uranyl nitrate as long as the former is dissolved ; the soln. thus obtained is orange-yellow in colour and very stable. The uranyl hydroxide here employed was obtained by exposing to light a mixture of uranyl acetate and ether and thoroughly washing the resulting precipitate. F. Mylius and R. Dietz also prepared the colloid by precipitating the chlorine from an aq. soln. of uranyl chloride, by means of silver oxide, and afterwards dialyzing the soln. The colloidal soln. so prepared has an astringent taste, reddens litmus, and when heated deposits dihydrated uranium trioxide. V. A. Kargin also prepared the hydrosol. B. Moore and T. A. Webster found that a dil. soln. of the colloid is a powerful catalyst in the synthesis of formic acid by exposing an aq. soln. of carbon dioxide to sunlight. K. C. Sen discussed the peptization of the hydrated oxide by sugars.

In the electrometric titration of 100 c.c. of a soln. of $0.00833M$-uranyl nitrate in $0.0149N$-HNO_3, H. T. S. Britton obtained the results summarized in Fig. 9. There is a slight inflexion in the curve with 14·9 c.c. of alkali, due to the presence of sexivalent uranium nitrate in the soln. With 45 c.c. of alkali the composition of the solute is $U(NO_3)_{2\cdot38}(OH)_{3\cdot62}$, and the soln. then becomes deeper yellow but clear ; with 55·8 c.c. of alkali, when the solute has the composition $U(NO_3)_{1\cdot08}(OH)_{4\cdot92}$, a yellow precipitate separates—*i.e.* when p_H is nearly 4·2. The deepening of the colour of the highly basic soln. is attributed to a gradual increase in the size of the basic particles of the solute, since the uranium hydroxide is held in soln. in a state closely akin to that of a colloid. The hydrion conc. of the soln. when 48 c.c. of alkali has been added is $10^{-3\cdot7}$; the soln. then contains the proportions

FIG. 9.—Electrometric Titration of Uranyl Nitrate Soln. with Sodium Hydroxide.

of uranium and nitrate present in uranyl nitrate, but is much deeper in colour than that obtained by dissolving uranyl nitrate crystals. The explanation of this difference probably lies in the fact that uranyl nitrate is crystallized from strongly acid soln. On soln. in water, it tends to revert to a state which is probably colloidal, as shown by the changes in colour and in con-ductivity which C. Dittrich found that it undergoes on standing and especially at high temp. If the increase in conductivity which takes place on standing is due to the formation of particles which are essentially colloidal, these particles must be capable of some kind of ionization. There seems to be very little support for the belief that uranyl salt soln. contain the uranyl-cation ; none is to be found in conductivity measurements, which show that the increases in conductivity with
dilution of soln. of the nitrate, chloride, and sulphate are anomalous. Precipitation is complete when 64 c.c. of alkali has been added, as compared with 64·7 c.c. which are required for the complete formation of uranic hydroxide. Hence the precipitate is uranic hydroxide containing a very small quantity of undecomposed nitrate. Dilute acid soln. of uranium nitrate or uranyl salt soln. themselves, when gently heated, undergo some profound change ; the colour becomes deeper and the reverse change on cooling takes place very slowly. They become alkaline to phenolphthalein when the theoretical amount of alkali is added, but a precipitate separates only when an appreciable excess of alkali has been added or the soln. has been boiled for some time. The opalescence of the alkaline colloidal soln. depends on the temp. to which the original soln. has been heated. The deep yellow soln. formed by gentle heating are almost clear, whereas those which have been boiled become visibly colloidal. If not too great an excess of alkali is added, the resulting colloidal soln. remains quite stable for several days. They are coagulable on addition of 1 or 2 c.c. of sat. potassium chloride soln. Heating thus appears to cause some change in the state of aggregation of the particles of uranium hydroxide, or more likely of highly basic salt, which are probably in equilibrium with free nitrate ions and are thereby enabled to enter into reaction with alkalies, so that the uranium hydroxide complexes remain in colloidal soln. P. Jolibois and R. Bossuet found that the precipitate obtained by the addition of soda-lye to a soln. of uranyl nitrate is not the diuranate, but the hydroxide associated with 1·2 to 8·0 per cent. of adsorbed alkali.

The observations of G. F. Hüttig and E. von Schröder on the vap. press. of hydrated uranium trioxide with an excess of water are summarized in Fig. 10, in the form of a dehydration curve. This shows that three hydrates can exist under these conditions. Observations were also made by A. Fischer and E. K. Rideal. At a little over 160°, the *hemihydrate*, $UO_3.\frac{1}{2}H_2O$, or $2UO_3.H_2O$, or **pyrouranic acid,** or **diuranic acid,** $H_2U_2O_7$, exists. This hydrate loses its water at 300°, forming uranium trioxide. According to L. Pissarjewsky, the heat of neutralization of a mol of pyrouranic acid by sodium hydroxide is 17·859 Cals. The *mono-hydrate*, $UO_3.H_2O$, or **uranyl hydroxide,** $UO_2(OH)_2$, or **uranic acid,** H_2UO_4, appears at about 96° on the dehydration curve of G. F. Hüttig and E. von Schröder, Fig. 10.

FIG. 10.—Dehydration Curve of Hydrated Uranium Trioxide.

J. J. Ebelmen obtained it as an orange-yellow product by heating the higher hydrate in vacuo at 100° ; and B. Drenckmann, by keeping it at 160° ; and R. de Forcrand, at 80°. It was also obtained by F. J. Malaguti, and C. F. Bucholz by drying the higher hydrate at 100°. F. J. Malaguti prepared it as an amorphous, lemon-yellow powder by heating an alcoholic soln. of uranyl nitrate for some time at a temp. below its b.p., and washing the precipitate. J. J. Berzelius, C. F. Bucholz, and J. Aloy heated uranyl nitrate on a sand-bath so long as nitrous fumes were evolved, and extracted soluble salts from the residue by repeatedly boiling it with water. J. Riban obtained crystals by heating a 2 per cent. soln. of uranyl acetate for 100 hrs. in a sealed tube at 175°. J. Aloy obtained this hydrate by exposing dihydrated uranium dioxide to air ; and also by heating the violet hydrate or uranosic oxide with water at 100° until it is completely converted into the yellow hydrate ; F. W. O. de Coninck, by the action of cold hydrogen dioxide on uranium dioxide ; C. Dittrich, by decomposing uranyl nitrate on a hot sand-bath and then boiling the product with water ; J. Zehenter, by exposing to air the violet precipitate obtained by the insolation of a soln. of uranyl acetate—the violet hydroxide soon passes into the yellow, monohydrated uranium trioxide ; and A. Mailhe, by digesting precipitated copper hydroxide with a soln. of uranyl nitrate. F. W. O. de Coninck and M. Camo electrolyzed a soln. of uranyl nitrate with a current of less than 1 amp., and obtained the orange monohydrate. S. J. Diachkowsky prepared

colloidal uranyl hydroxide by the hydrolysis of uranates and dialysis in running water. Dehydration leads to coagulation of the hydrosol resulting in the precipitation of a hydrate of uranic acid. When hydration is complete, the precipitate formed on coagulation corresponds with $Na_2U_2O_7$. In either case on treatment with water a colloidal soln. is again formed. The whole synthesis can be represented: $nNa_2U_2O_7 \rightleftharpoons [Na_2U_2O_7.H_2UO_4]_{n-1} \rightleftharpoons [H_2O(UO_3)_2UO_2(OH)_2]_n \rightleftharpoons [UO_2(OH)_2]_{n+1}$, the equilibrium being disturbed if sodium diuranate or uranic acid is removed from the sphere of reaction. The particles are negatively charged and their velocity in an electric field corresponds with a charge of 1.984×10^{-8} e.s.u. The density of the sol is 7.45, and the size of the particles varies from 1.144×10^{-15} to one amicron, showing that the system is polydisperse. Hydrochloric acid, barium chloride, and aluminium chloride coagulate the sol; and with aluminium chloride the sign of the charge changes. K. C. Sen discussed the retardation in the peptization of the colloid by the presence of sugar.

J. Aloy said that he obtained the hydrate in yellow, microscopic, rhombic plates; and J. Riban, in yellow, six-sided prisms or plates. According to F. W. O. de Coninck and M. Camo, the sp. gr. is 5.926 at 15°. J. J. Ebelmen found that the monohydrate loses its water completely at 300°; F. J. Malaguti, that one-third of the water is lost at 400°, and all at a higher temp. Oxygen is given off at the same time, forming uranosic oxide, etc. G. F. Hüttig and E. von Schröder's observations on this subject are summarized in Fig. 10. G. F. Hüttig gave for the heat of formation of the hydrates, $(UO_3, \frac{1}{2}H_2O)=13.29$ Cals.; $(UO_3, H_2O)=23.4$ Cals.; $(UO_3, 1\frac{1}{2}H_2O)=31.74$ Cals.; and $(UO_3, 2H_2O)=39.24$ Cals. R. de Forcrand gave 14.846 Cals. for the heat of soln. of the monohydrate in dil. nitric acid. According to J. Aloy, the heat of neutralization of $UO_3.H_2O+HCl$, etc., with $0.5N$-soln. of the acids is with hydrochloric acid, 8.4 Cals.; with hydrobromic acid, 8.8 Cals.; with nitric acid, 8.4 Cals.; with sulphuric acid, 9.5 Cals.; and with acetic acid, 7.5 Cals. According to C. A. Pierlé, the electrode potential of the hydrate, $UO_3.H_2O$, against a soln. of 14.3 grms. of uranyl nitrate per litre, is -0.860 volt. J. Aloy observed that it is reduced to uranium dioxide when heated in hydrogen, and that it is easily soluble in dil. acids. F. W. O. de Coninck found that the hydrate reacts with calcium oxalate, at a red-heat, in accord with: $CaC_2O_4+UO_3.H_2O$ $=CaCO_3+CO_2+UO_2+H_2O$.

J. J. Ebelmen prepared the *dihydrate*, $UO_3.2H_2O$, or *hydrated uranic acid*, $H_2UO_4.H_2O$, by exposing a soln. of uranyl oxalate to sunlight until the violet-brown precipitate is yellow, and then drying it in air; and by boiling a soln. of ammonium uranyl carbonate until it falls as a yellow precipitate, or, according to B. Drenckmann, by allowing a soln. to stand for 9 months with a limited access of air; J. Aloy, by the slow oxidation in air of the violet hydrate of uranosic oxide; B. Drenckmann, by heating a mixture of potassium chlorate and uranosic oxide up to the m.p., and when cold, boiling the product repeatedly with water; F. Mylius and R. Dietz, by boiling the colloidal soln.; J. Aloy, by heating uranosic oxide with water; F. W. O. de Coninck, by heating uranium dioxide with hydrogen dioxide; and P. Lebeau, by evaporating a soln. of uranyl nitrate at ordinary temp. over sulphuric acid, and then extracting the residue with ether. The dihydrate appears as a lemon-yellow powder; and J. Aloy obtained it in rhombic, rectangular plates and prisms. According to H. Rose, the dihydrate reddens moist litmus paper—*vide supra*, colloidal uranium trioxide. T. L. Walker described a lemon-yellow mineral from Kasolo, Katanga, Belgian Congo, which he called **schoepite**—after A. Schoep. Its composition was found by A. Schoep to approximate $UO_3.2H_2O$; the rhombic crystals have the axial ratios $a:b:c=0.426:1:0.875$. The sp. gr. is 5.685. The (001)-cleavage is perfect; there is no pleochroism. V. Billiet found that the indices of refraction are $a=1.690$, $\beta=1.714$, and $\gamma=1.735$. It is optically negative. A. Schoep said that **becquerelite**—*vide infra*, lead uranate —is a similar mineral from the same locality, and that the axial ratios of the rhombic crystals are $a:b:c=0.5537:1:0.5938$, with a perfect cleavage parallel to (001),

and a less marked cleavage parallel to (101). Becquerelite contains over 5 per cent. of lead oxide as impurity, whilst schoepite rarely contains 1 per cent. The two minerals show that the dihydrate, $UO_3.2H_2O$, is dimorphous. Becquerelite loses half its water at 150° and the remainder at 500°, whilst schoepite loses half its water at 110° and all at 325°—*vide infra*, fourmarierite. S. C. Lind and C. W. Davis described a mineral which they called *lambertite*—after R. Lambert— and which occurred at Silver Cliff Hill, Lusk, Wyoming. It is said to be hydrated uranium trioxide, but E. S. Larsen and co-workers found that lambertite is nothing but *uranophane*, $CaO.2UO_3.2SiO_3.6H_2O$. According to J. J. Ebelmen, and B. Drenckmann, the dihydrate is stable in air, and it does not absorb carbon dioxide from the atm.; and it loses a mol. of water at 100° to 160°, and at 300° passes into uranium trioxide—*vide supra*, the monohydrate. G. F. Hüttig and E. von Schröder's observations on this subject are summarized in Fig. 10. R. de Forcrand gave 12·375 Cals. for the heat of soln. in dil. nitric acid. A. Schoep described a mineral found in the cavities of a specimen of uraninite from Katanga, Belgian Congo. The mineral was called **ianthinite**—from ἰάνθινος, violet coloured. It forms acicular rhombic crystals with the axial ratios $a:b:c=2\cdot5938:1:—$. The cleavage is micaceous and the colour violet-black with a brownish-violet streak. The pleochroism is strong, a, colourless, b, dark violet, and c, violet. The indices of refraction are $a=1\cdot674$, $\beta=1\cdot90$, and $\gamma=1\cdot92$. V. Billiet gave 1·64, 1·92, and 1·90 respectively. Its composition approximates to the *hemiheptahydrate*, $2UO_3.7H_2O$.

Uranium trioxide is amphoteric. All the hydrates dissolve in acids to form yellow soln. of *uranyl salts*; whilst with inorganic and organic bases uranium trioxide forms *uranates*. W. R. E. Hodgkinson and F. K. S. Lowndes observed that when the hydrate is heated with potassium chlorate, chlorine is given off and potassium diuranate is formed. M. E. Chevreul found that uranic acid reddens litmus as acids do, but affects hematine-blue as do salifiable bases.

§ 12. The Normal Uranates, or Monouranates

Uranic acid, H_2UO_4, behaves as a dibasic acid, forming salts of the type R_2UO_4; and, like the other acids of the same family of elements, it forms more acid salts, $R_2O.nUO_3$, in which n may be 2, 3, 4, 5, and 6. With the exception of pyrouranic acid, or diuranic acid, $H_2U_2O_7$, the corresponding acids are unknown. The acid salts are probably constituted like the corresponding molybdic and tungstic salts; but they have not yet been investigated. Only salts of the more electropositive metals have been prepared.

Normal *ammonium uranate*, $(NH_4)_2UO_4$, has not been prepared, although acid salts are known. K. A. Hofmann[1] prepared anhydrous **hydroxylamine uranate,** $(NH_3OH)_2UO_4$, as a golden-yellow, amorphous powder, by heating the ammine— *vide infra*—with glycerol at 100°. The product is washed with alcohol and ether. The *monohydrate*, $(NH_3OH)_2UO_4.H_2O$, is formed by allowing the ammine to remain for some hours in contact with water at ordinary temp., or by treating the ammine with hot water, or by treating it with acetic acid. K. A. Hofmann obtained it by digesting uranic acid or uranyl nitrate with an excess of an aq. soln. of hydroxylamine; and V. Kohlschütter and K. Vogdt, by adding hydroxylamine hydrochloride to the orange precipitate produced by adding alkali-lye to a soln. of a uranyl salt. H. Gubler modified the process, and also added dil. aq. ammonia to a soln. of 50 grms. of uranyl nitrate in 200–300 c.c. of water, with constant stirring until the uranium is all precipitated as ammonium uranate. A soln. of 14–15 grms. of hydroxylamine hydrochloride in 50 c.c. of water is then added; and after standing half an hour, the precipitate is filtered, and washed twice with alcohol, and ether. There is generally a dark decomposition product formed in these processes. The hydroxylamine uranate obtained by V. Kohlschütter and K. Vogdt appeared in yellowish-green crystals; whilst that prepared by K. A. Hofmann appeared in yellow, elongated plates, pointed at both ends at an angle of 120°. When heated the salt decomposes with a slight explosion, producing a greenish-black powder. V. Kohlschütter and K. Vogdt said that when slowly heated at 125°, it decomposes into water and ammonia, which pass away, and into nitrogen and nitrous oxide, which remain practically entirely dissolved in the uranic acid, and escape on dissolving the residue in dil. acids. Uranium oxide only exercises this power of retaining indifferent gases so long as it contains traces of water, the real solvents being hydrates of uranium trioxide. It is suggested that the water

present plays an important part in the retention of such gases as helium in uranium minerals. On the other hand, C. Friedheim suggested that the product obtained by heating hydroxylamine uranate at 125° is not a solid soln. of nitrogen and nitrous oxide in uranic acid, but that the decomposition proceeds : $UO_2(O.NH_3OH)_2$ →UO_2 : $(O.NH_3)_2$: O. Hydroxylamine uranate is known to behave as an acid, and the compound obtained by the action of heat may be regarded as an anhydride, so that the residue after heating consists of this anhydride mixed with a certain amount of uranic acid. The action of sulphuric acid on the anhydride is to yield uranyl sulphate and $(HO.NH_3)_2O$. This latter loses water, yielding the anhydride of hydroxylamine, $(NH_2)_2O$, which immediately decomposes into nitrogen, nitrous oxide, ammonia, hydrogen, and water. The hydrogen is probably used up in reducing uranium trioxide. H. Gubler said that the salt does not explode at 100° when out of contact with oxygen ; but if heated to 100° in a current of oxygen, uranic acid remains as a residue, while hydroxylamine is given off, and this decomposes into steam and an equal vol. of nitrogen and nitrous oxide. If the temp. exceeds 100°, some ammonia is formed as well ; but if no oxygen is present and the water vapour is removed by a current of inert gas, steam, ammonia, and hydrogen are formed. K. A. Hofmann found that the salt readily reduces Fehling's soln. V. Kohlschütter and K. A. Hofmann added that the brownish-black substance which is formed when hydroxylamine uranate is dehydrated at 125° is **uranium pentoxynitride,** UO_5N, a substance which liberates a mixture of nitrogen and nitrous oxide when treated with cold dil. acids, uranic acid passing into soln. According to K. A. Hofmann, **hydroxylamine diamminouranate,** $(NH_3OH)_2UO_4.2NH_3$, is obtained by adding 100 c.c. of 7 per cent. aq. ammonia to an aq. soln. of 20 grms. of uranyl nitrate and 10 grms. of hydroxylamine hydrochloride. The product is washed successively with dil. ammonia, alcohol, and ether. The constitution is represented by the formula $UO_2(O.NH_3.O.NH_4)_2$. The amminouranate is a lustrous, canary-yellow, crystalline powder consisting of microscopic, rhombic tablets ; it is stable at the ordinary temp., loses ammonia when heated at 73°, and decomposes with a slight explosion when heated to 178°–180° in a capillary tube. It reduces Fehling's soln. at the ordinary temp., and when cautiously heated to 120° is converted into uranic acid, H_2UO_4. The ammonia is readily expelled when the salt is treated with water as indicated above ; the uranic acid is not reduced when the salt is boiled with soda-lye. These facts are taken to confirm the above formula. When the amminouranate is treated with 2 mols. of acetic acid, it yields ammonium acetate and hydroxylamine uranate ; with an excess of acetic acid, it yields a double salt of uranyl acetate and hydroxylamine acetate, which crystallizes in yellow, lustrous prisms.

According to V. Kohlschütter and K. A. Hofmann, **potassium hydroxylamine hydrouranate,** $(NH_3OH)(NH_3OK)UO_4.H_2O$, is obtained by dissolving 10 grms. of uranyl nitrate and 15 grms. of hydroxylamine hydrochloride in 100 c.c. of water, and adding a 10 per cent. soln. of potash-lye until the yellow, flocculent precipitate at first formed is redissolved ; reddish-yellow cubes separate slowly from the liquid, precipitation being hastened by adding alcohol. The substance disintegrates to a yellow powder when heated, and has an ammoniacal smell ; it is sparingly soluble in water, and is oxidized slowly by Fehling's soln. Turmeric is coloured brown by dil. soln. When the potassium compound is digested with water which has been sat. with carbon dioxide, the colour changes to green and hydroxylamine uranate is produced. The corresponding **sodium hydroxylamine hydrouranate,** $(NH_3OH)(NH_3ONa)UO_4.H_2O$, is obtained in minute prismatic crystals in a similar manner ; and the mother-liquor deposits **sodium hydroxylamine uranate,** $(NH_3ONa)_2UO_4.6H_2O$, in orange-red rosettes of prisms, and dissolves in its water of crystallization when heated ; it is readily soluble in water, and vigorously reduces Fehling's soln.

A. Ditte [2] prepared **lithium uranate,** Li_2UO_4, by fusing together a mixture of lithium chloride and uranosic oxide, and extracting the cold product with water.

J. L. C. Zimmermann prepared lithium uranate by heating a mixture of lithium and ammonium chlorides with uranyl chloride at a high temp. The product, when cold, is washed with cold water. Whilst potassium and sodium chlorides under similar conditions give the diuranates, lithium chloride forms the normal salt. Lithium uranate is far more easily decomposed by hot water than the corresponding sodium or potassium salts; lithium and uranyl hydroxides are produced. G. Tammann and W. Rosenthal prepared lithium uranate by heating mol. proportions of lithium carbonate and uranium trioxide to 600°. The reaction begins at 380°. B. Drenckmann obtained **sodium uranate,** Na_2UO_4, by heating sodium diuranate with a large excess of sodium chloride; A. Ditte, by heating uranosic oxide with sodium carbonate or chloride with or without sodium chlorate; T. Poleck, by boiling the yellow soln. of sodium perdiuranate, obtained by fusing a uranyl salt with sodium dioxide; and L. Michel, by heating uranium molybdate with sodium chloride. J. L. C. Zimmermann converted the amorphous salt into crystals by fusing it with sodium chloride. A. Ditte said that the salt forms greenish-yellow plates, and L. Michel, reddish-yellow, doubly refracting, rhombic prisms with a cleavage on the (110)-face, and the optic axial angle $2E=59°$. W. G. Mixter gave for the heat of formation, $(UO_3,Na_2O)=96\cdot1$ Cals.; $(UO_2,Na_2O_2)=110\cdot9$ Cals.; and $U_3O_8+Na_2O_2+2Na_2O=3Na_2UO_4+285\cdot1$ Cals. A. Ditte added that the salt is insoluble in water, and freely soluble in acids. A. Ditte prepared normal **potassium uranate,** K_2UO_4, as in the case of the sodium salt, namely, by fusing together a mixture of potassium chloride and uranosic oxide; if the mixture in a platinum crucible be heated from below, the uranate separates as a crystalline crust at the surface, and can be washed free from chlorides by water. H. Grandeau obtained it by fusing a mixture of uranyl phosphate and potassium sulphate; J. L. C. Zimmermann, by fusing a mixture of 6 parts of uranyl chloride, 16 parts of ammonium chloride, and 4 parts of potassium chloride; and O. Brunck, by heating together a mixture of uranium trioxide and potassium chlorate. The products washed free from soluble matters furnish, according to H. Grandeau, orange-yellow, pseudo-hexagonal plates. The crystals are rhombic, with the optic axial angle $2E=110°$, approximately. A. Ditte obtained **rubidium uranate,** Rb_2UO_4, by fusing rubidium chloride and uranosic oxide as in the case of the potassium salt. G. Tammann and W. Rosenthal found that a mixture of mol. proportions of copper oxide, or of silver oxide, and uranium trioxide begins to react, forming brown **copper uranate,** $CuUO_4$, at 340°, and brown **silver uranate,** Ag_2UO_4, at 150° respectively.

F. W. O. de Coninck prepared **calcium uranate,** $CaUO_4$, as a dark red precipitate, by adding ammonia to a mixed soln. of uranyl chloride and calcium chloride: $UO_2Cl_2+CaCl_2+4NH_3+2H_2O=CaUO_4+4NH_4Cl$, and A. Ditte, by heating a mixture of uranosic oxide and calcium chloride—free from oxide. G. Tammann and W. Rosenthal found that the formation of calcium uranate begins at 160° when a mixture of mol. proportions of the constituent oxides is heated. According to A. Ditte, the greenish-yellow plates are insoluble in water, but soluble in dil. acids. If heated to redness for a long time the colour deepens, and the compound dissolves less readily in dil. acids. By using processes analogous to those employed for calcium uranate, F. W. O. de Coninck, and A. Ditte prepared **strontium uranate,** $SrUO_4$; also **barium uranate,** $BaUO_4$. J. A. Hedvall and N. von Zweigbergh observed that a mixture of barium dioxide and uranium trioxide begins to give off oxygen at 250°. G. Tammann and W. Rosenthal found that the normal uranates begin to form when a mixture of mol. proportions of uranium trioxide and strontium oxide is heated to 125°, and with barium oxide the reaction begins at 240°. No **beryllium uranate** was observed by heating a mixture of mol. proportions of the constituent oxides to 600°; but yellow **magnesium uranate,** $MgUO_4$, was obtained. A. Ditte also prepared magnesium uranate. I. Wertheim found that **zinc uranate,** $ZnUO_4$, is deposited on a sheet of zinc immersed in a soln. of uranyl nitrate; and it is deposited when zinc uranyl acetate is treated with baryta-water. M. Kohn observed that when a boiling conc. soln. of uranyl nitrate is treated with basic

zinc carbonate, and the yellow precipitate is washed successively with water, alcohol, and ether, the product consists of hydrated uranium trioxide contaminated with zinc oxide. G. Tammann and W. Rosenthal found that the formation of zinc uranate begins when a mixture of mol. proportions of the constituent oxides is heated to 200° ; with orange-yellow **cadmium uranate,** $CdUO_4$, the reaction begins at 425° ; with orange-yellow **mercuric uranate,** $HgUO_4$, at 175° ; and with yellow **aluminium uranate,** $Al_2(UO_4)_3$, at 450°. C. Renz found that **indium uranate** is precipitated from a soln. of an indium salt when it is treated with a soln. of sodium uranate ; and H. C. Bolton obtained a yellow precipitate of **thallous uranate,** resembling the alkali uranates, when thallous hydroxide is added to a soln. of a uranyl salt. G. Tammann and W. Rosenthal observed that **cerium uranate** is not formed when an equimolar mixture of cerium and uranium trioxides is heated to 600°.

The canary-yellow or orange-yellow crystalline crusts found on the pitchblende from Kasolo, Katanga, Belgian Congo, were called by A. Schoep **becquerelite**—after H. Becquerel. The minute rhombic crystals have the axial ratios $a : b : c$ $=0.5537 : 1 : 0.5938$, and are like schoepite, $UO_3.2H_2O$, but contain a higher proportion of lead. S. G. Gordon, re-orienting the measurements, obtained $a : b : c$ $=0.432 : 1 : 0.874$, virtually the same as schoepite. When dried at 100° becquerelite corresponds with a kind of **lead uranate,** or it may be the hydrated trioxide with some uranyl replaced by lead, namely, $(UO_2.Pb)O$, $2H_2O$—*vide supra*, schoepite. The crystals of becquerelite may be twinned after the aragonite type ; the (001)- and (110)-cleavages are perfect ; the indices of refraction $\alpha=1.75$, and $\gamma=1.77$; the optical character is negative ; and the pleochroism ranges from colourless to deep yellow. V. Billiet gave 1.750, 1.88, and 1.87 for the indices of refraction of the rhombic crystals. G. Tammann and W. Rosenthal observed that a mixture of mol. proportions of lead oxide and uranium trioxide begins to react at 375°, forming lead uranate. Normal lead uranate, $PbUO_4$, was prepared by I. Wertheim, and C. F. Rammelsberg by calcining lead acetate and a uranium salt at a dull red-heat. J. Zehenter said that the reddish-brown mass consists of microscopic needles. It becomes black when heated to bright redness. The salt is insoluble in water, potash-lye, aq. ammonia, alcohol and ether ; sparingly soluble in cold acetic acid ; and freely soluble in nitric acid and hot acetic acid. According to K. C. Bailey, lead uranate is insoluble in boiling distilled water, or in a boiling soln. of sodium chloride, but in both cases some lead salt passes into soln. when the system is exposed to α-rays. The reaction was discussed by A. Holmes. J. Melon found that the composition of the rhombic crystals is $PbO.5UO_3.10H_2O$, and V. Billiet found the indices of refraction to be $\beta=1.92$ and $\gamma=1.94$. C. S. Ross, E. P. Henderson and E. Posnjak described a mineral from Spruce Vine, Carolina, which they called **clarkeite**—after F. W. Clarke. Its composition approximates $(Na_2,Ca,Pb)O.3UO_3.3H_2O$. It is reddish-brown and massive ; without cleavage, and with a conchoidal fracture. It is considered to be a direct alteration product of uraninite, gummite and uranophane being later products.

For **vanadium uranate,** *vide* uranyl vanadate. V. A. Kargin studied the complex salts formed by uranium trioxide with vanadium pentoxide. G. Tammann and W. Rosenthal observed that green vanadium uranate, $V_2(UO_4)_3$, begins to form at 290° when a mixture of mol. proportions of the constituent oxides is heated ; with **chromium uranate,** $Cr_2(UO_4)_3$, the reaction begins at 230° ; with **manganous uranate,** $MnUO_4$, at 450° ; and the brown **ferric uranate,** $Fe_2(UO_4)_3$, is formed at 600°. J. A. Arfvedson passed ammonia into a soln. containing ferric and uranyl salts, and heated the precipitate in hydrogen. He called the product *iron uranate.* It appears to be a mixture of iron and uranium oxides. G. Tammann and W. Rosenthal found that **cobalt uranate,** $CoUO_4$, is formed when an equimolar mixture of the constituent oxides is heated to 600°—the reaction begins at 230° ; in the formation of **nickel uranate,** $NiUO_4$, the reaction begins at 340°.

§ 13. The Polyuranates

According to J. A. Arfvedson,[1] **ammonium diuranate,** $(NH_4)_2U_2O_7$, is obtained as a hydrated yellow powder when uranyl nitrate or chloride is treated with an excess of aq. ammonia. A. J. Carson and T. H. Norton prepared the salt in a similar way, and dried the product at 100°. They said that there is a marked difference between the observed and theoretical proportions of uranium with the uranates of ammonium, and of methyl-, dimethyl-, trimethyl-, ethyl-, diethyl-, triethyl-, isobutyl-, and phenyl-ammonium—the ethyl-ammonium salt approaches nearest to the theoretical value. Ammonium diuranate is the ammonium uranate of commerce, where it, as well as the sodium salt, is known as *uranium yellow.* A. Patera, and E. Vysoky described the preparation of the two uranium yellows. The ammonium salt is obtained commercially by boiling a soln. of sodium uranyl carbonate with ammonium sulphate, or by boiling sodium diuranate with a conc. soln. of ammonium chloride. Ammonium diuranate is a deep yellow powder which, according to J. A. Arfvedson, can be dried at 100° without change, but at a higher temp. it is resolved into nitrogen, ammonia, water, and uranosic oxide; if it is heated with ammonium chloride, F. Stolba found that an appreciable quantity of uranium volatilizes with the ammonium salt. J. J. Berzelius said that it is very sparingly soluble in water, but it is not soluble in water containing ammonium chloride, and J. A. Arfvedson said that it is insoluble in aq. ammonia. These facts are sometimes utilized in the analytical separation of uranium; the salt cannot be freed from ammonia by boiling it with water. E. M. Péligot observed that the diuranate is soluble in a soln. of ammonium carbonate, forming ammonium uranyl carbonate.

H. von Unruh obtained anhydrous **sodium diuranate,** $Na_2U_2O_7$, by adding sodium to an ethereal soln. of uranyl nitrate, $6Na+2UO_2(NO_3)_2.6H_2O$ $=4NaNO_3+3H_2+3H_2O+Na_2U_2O_7$. I. Wertheim obtained the anhydrous salt by heating the hydrated salt obtained commercially by A. Patera, E. F. Anthon, F. Stolba, L. Kessler, K. A. Hofmann and E. Strauss, and F. J. Metzger and M. Heidelberger, as indicated in connection with the extraction of uranium from its ores. J. L. C. Zimmermann obtained it by a process similar to that which he employed for normal lithium uranate. It is isomorphous with the corresponding potassium salt. F. Stolba, and A. Patera obtained the *hexahydrate* by adding an

excess of sodium hydroxide to a soln. of a uranyl salt, and drying the washed precipitate in air. A. Lancien obtained it by boiling uranyl molybdate in soda-lye for a long time. The light yellow *uranium yellow* of commerce—*vide supra*, the ammonium salt—is obtained by decomposing a soln. of sodium uranyl carbonate with sulphuric acid ; and the *orange-yellow*, by decomposing a uranyl salt with an excess of sodium hydroxide. According to F. J. Metzger and M. Heidelberger, sodium uranate, of the composition $Na_2U_2O_7$, may actually be precipitated, but on washing with water to remove the excess of alkali, it gradually undergoes partial hydrolysis, so that pure sodium uranate, obtained by adding sodium hydroxide to a soln. of uranyl nitrate, has the composition $Na_4U_5O_{17}$, and A. Patera's precipitate the composition $Na_9U_{10}O_{35}$. J. A. Arfvedson prepared **potassium diuranate,** $K_2U_2O_7$, by treating a soln. of a uranyl salt with an excess of potash-lye, and calcining the washed product at a red-heat. P. Jolibois and R. Bossuet found that the precipitate from uranyl nitrate soln. with soda-lye is not the diuranate, the precipitate contains no nitrate, and 1·2 to 8 per cent. of adsorbed alkali. H. T. S. Britton also showed that the precipitate is probably uranium hydroxide. J. J. Berzelius obtained the diuranate by melting uranium trioxide with an excess of potassium carbonate, and extracting the cold mass with water ; and also by calcining potassium uranyl carbonate, and I. Wertheim, by calcining potassium uranyl acetate, and extracting the products with water. J. L. C. Zimmermann, and A. Lancien obtained it by processes analogous to those used for the sodium salt. The colour varies from brick-red to orange-yellow according to the mode of preparation. J. L. C. Zimmermann described it as a crystalline powder with the crystals probably rhombic and isomorphous with those of the sodium salt. The salt becomes dark red when heated, but the original colour is restored on cooling. J. L. C. Zimmermann, and F. W. O. de Coninck observed that the salt is insoluble in water and freely soluble in acids. According to A. Patera, if the precipitated salt is dried at 100°, the *trihydrate* is formed ; and, according to F. Stolba, if dried in air, at ordinary temp., the *hexahydrate*. L. Fernandes obtained a complex with gallic acid.

C. F. Rammelsberg obtained a brick-red precipitate by adding aq. ammonia to a mixed soln. of uranyl nitrate and an excess of silver nitrate. A. Guyard, and G. Alibegoff obtained **silver diuranate,** $Ag_2U_2O_7$, by the action of freshly-precipitated silver oxide on a soln. of uranyl nitrate ; G. Alibegoff, by the action of potassium uranate on fused silver nitrate ; and I. Wertheim, by boiling uranyl silver acetate with water. The orange-red product is decomposed by hydrochloric acid. J. Aloy said that a basic silver uranate is produced when uranic acid is digested with a soln. of silver nitrate. A. Ditte prepared **calcium diuranate,** CaU_2O_7, by heating a mixture of uranosic oxide and calcium chlorate, and fusing the product with sodium or calcium chloride so as to convert the amorphous salt into greenish-yellow plates. A. Ditte prepared **strontium diuranate,** SrU_2O_7, by an analogous process. According to a communication by " J.," the brownish-red product is sparingly soluble in water and soluble in acids, including oxalic acid. J. A. Arfvedson added barium chloride and an excess of ammonia to a boiling soln. of uranyl chloride, washed the product with boiling water, and obtained what was presumably **barium diuranate,** BaU_2O_7, which J. J. Berzelius obtained by adding barium chloride to a soln. of ammonium diuranate ; and J. J. Berzelius, and O. B. Kühn, by adding an excess of baryta-water to a soln. of uranyl nitrate. I. Wertheim used uranyl acetate with an insufficient amount of baryta-water to precipitate all the uranium ; the idea was to avoid the formation of barium carbonate ; he also obtained the diuranate by heating barium uranyl acetate to redness. A. Ditte prepared the salt by heating uranosic oxide with barium chlorate ; and J. Zehenter, by heating barium uranyl acetate between 300° and a red-heat. The yellowish-red crystalline powder is decomposed by hydrogen at a red-heat. I. Wertheim obtained **magnesium diuranate,** MgU_2O_7, as a yellowish-brown powder, by calcining magnesium uranyl acetate ; and J. J. Berzelius, by adding ammonia

to a mixed soln. of uranyl nitrate and magnesium nitrate. K. A. Hofmann and K. Höschele obtained magnesium diuranate, $Mg_3U_2O_9$, by fusing anhydrous magnesium chloride with uranic acid. J. A. Arfvedson obtained **lead diuranate,** PbU_2O_7, by adding aq. ammonia to a mixed soln. of lead and uranyl nitrates ; I. Wertheim, by boiling freshly-precipitated lead carbonate with a soln. of uranyl nitrate, and then with the acetate ; J. Persoz, by adding uranyl nitrate to a soln. of lead acetate ; and J. Zehenter, by boiling a dil. soln. of lead uranyl acetate in a reflux apparatus, whereby golden-yellow crystals of the hemipentahydrate, $PbU_2O_7.2\frac{1}{2}H_2O$, are formed—they become anhydrous on ignition. The yellowish-red or brownish-red salt which has been heated is sparingly soluble in acetic acid. J. Zehenter represented it by the formula :

$$Pb\diagdown^{O.UO_2}_{O.UO_2}\diagup O$$
A. Weisbach found a mineral near Schneeberg, Saxony, occurring in half globular, aggregated forms, made up of minute, acutely terminated crystals of **bismuthyl diuranate,** $(BiO)_2U_2O_7.3H_2O$, or $Bi_2O_3.2UO_2.3H_2O$, according to the analysis of C. Winkler. The mineral was called **uranosphærite.** Its colour is orange-yellow to brick-red ; its sp. gr., 6·36 ; and its hardness, 2·3. A. L. Fletcher said that small particles soften at 1170°, and large particles melt at 1320°.

B. Drenckmann [2] prepared **sodium triuranate,** $Na_2O.3UO_3$, by heating a mixture of uranyl sulphate and sodium chloride, and washing the residue with water. The hygroscopic golden-yellow powder consists of rhombic crystals of sp. gr. 6·912. It becomes silver-grey when heated to a high temp. It is insoluble in water, but freely soluble in dil. acids. J. Zehenter obtained **barium triuranate,** $BaU_3O_{10}.4\frac{1}{2}H_2O$, by boiling a soln. of barium uranyl acetate. The yellow crystalline mass loses $2\frac{1}{2}H_2O$ at 140°, and the remaining 2 mols. at low redness.

According to N. A. Orloff, **neodymium triuranate,** $Nd_2(U_3O_{10})_3.18H_2O$, is formed as a yellow crystalline precipitate on heating on a water-bath neodymium hydroxide with a soln. of uranyl acetate ; and similarly with **praseodymium triuranate,** $Pr_2(U_3O_{10})_3.18H_2O$. The corresponding **aluminium triuranate** is not formed in this way. J. Zehenter obtained **lead triuranate,** PbU_3O_{10}, by calcining lead triuranyl acetate. The reddish-brown microscopic prisms are insoluble in water, potash-lye, aq. ammonia, and cold acetic acid ; but soluble in nitric acid and hot acetic acid. The constitution is represented :

$$UO_2\diagdown^{O.UO_2.O}_{O.UO_2.O}\diagup Pb$$
According to H. Gubler,[3] if uranyl acetate be dissolved in a little very dil. hydrochloric acid, filtered, mixed with an excess of ammonia, and the gelatinous precipitate dried on a porous tile, there is produced pale orange-yellow **ammonium tetrauranate,** $(NH_4)_2O.4UO_3.7H_2O$. J. Zehenter obtained **potassium tetrauranate,** $K_2O.4UO_3.5H_2O$, by evaporating an aq. soln. of potassium uranyl acetate, with the frequent addition of water, until the soln. is no longer acid. The yellow crystalline powder resembles the hexauranate in its properties. It loses about 2 mols. of water at 110°, and the rest at dull redness. A. Schoep described a reddish-brown mineral from Belgian Congo, and he called it **fourmarierite**—after P. Fourmariér. It occurs in rhombic crystals with axial ratios $a : b : c = 0.8832 : 1 : 0.8115$. The mineral is dichroic, and has a perfect cleavage perpendicular to the inclined axis. Its chemical composition approximates $PbO.4UO_3.5H_2O$, **lead tetrauranate,** but since the proportion of lead varies, he prefers to write it $(Pb,UO_2)O.H_2O$— *vide infra,* becquerelite and schoepite, which can also be represented by this formula. Its sp. gr. is 6·046 ; hardness, 3 to 4 ; and index of refraction >1·754—V. Billiet gave 1·94–1·92 for the rhombic crystals. No water is lost at 100°, but all the water and some oxygen are lost at 350°. Some specimens contain up to 0·67 per cent. tellurium trioxide, and a little ferric oxide is usually present.

According to J. Zehenter,[4] when an aq. soln. of sodium uranyl acetate is boiled, an orange-yellow powder of **sodium pentauranate,** $Na_2O.5UO_3.5H_2O$, is deposited. The *pentahydrate* consists of rounded granules and six-sided plates. When heated, the yellow powder becomes brownish-yellow, and then dirty grey. It loses most of its water of crystallization over conc. sulphuric acid, or in vacuo, or at 100°; the remainder is driven off at a red-heat. It is insoluble in water, alcohol, aq. ammonia, and potash-lye, but freely soluble in hydrochloric, sulphuric, and nitric acids, and less soluble in hot acetic acid. F. Stolba reported a *dodecahydrate* to be formed by adding sodium hydroxide, not in excess, to a soln. of uranyl sulphate, and drying the precipitate in air. J. Zehenter found that **barium pentauranate,** $BaU_5O_{17}.8H_2O$, is formed in golden-yellow crystals by heating a soln. of barium uranyl acetate on a water-bath and replacing the water evaporated from time to time. The crystals lose $4\frac{1}{2}H_2O$ at 140°, and the remainder at dull redness. A. Schoep reported a reddish-brown mineral occurring in acicular crystals, and also massive at Kasolo, Katanga, Belgian Congo ; as translucent, reddish-brown, acicular crystals on torbernite; or else in compact, earthy masses consisting of minute needles. The mineral is called **curite**—after P. Curie—and the analysis corresponds with **lead pentauranite,** $2PbO.5UO_3.4H_2O$. The axial ratios of the rhombic crystals are $a : b : c = 0.9553 : 1 : 0.6535$, and the (100)- and (110)-cleavages are good. V. Billiet gave 2.12, and 2.07 for the index of refraction of the rhombic crystals. The sp. gr. is 7.192 at 17°; the hardness, 4 to 5 ; the index of refraction, >1.74. V. Billiet gave $\beta = 2.07$, and $\gamma = 2.12$. A. Schoep observed that when heated, the mineral becomes dark brown ; it is soluble in cold nitric acid and in hot hydrochloric acid. J. Zehenter obtained the salt $4PbO.5UO_3.4H_2O$, by heating a dil. soln. of lead uranyl acetate on a water-bath, replacing from time to time the water as it evaporates. The slow evaporation of the soln. furnishes a golden-yellow, micro-crystalline powder resembling lead uranate in its general properties. It becomes anhydrous at dull redness. W. Vernadsky and C. Chamié considered curite to be an alteration product of pitchblende.

According to J. Zehenter,[5] ammonium uranyl acetate in aq. soln. decomposes in a short time, or at once on heating or evaporation, forming **ammonium hexa-uranate,** $(NH_4)_2O.6UO_3.10H_2O$, as a yellow powder, which consists of microscopic granules and six-sided plates. It loses 6 mols. of water at 120°, and at a higher temp. ammonia and water are given off, leaving uranosic oxide. The salt is insoluble in hot or cold water and in alkali-lye, but is freely soluble in hydrochloric, sulphuric, and acetic acids. According to R. Salvadori, when a 50 per cent. soln. of hydrazine hydrate is added to an aq. soln. of uranyl nitrate, **hydrazine pentauranate,** $(N_2H_5)_2O.5UO_3.8H_2O$, is precipitated. It loses almost all its nitrogen at 100°. B. Drenckmann prepared **potassium hexauranate,** $K_2O.6UO_3.6H_2O$, by heating over a blast gas-flame a mixture of potassium chloride and uranyl sulphate containing an excess of sulphuric acid, and the whole being covered by a layer of potassium chloride. The product was slowly cooled and boiled with water. The residue dried in vacuo furnished a hygroscopic yellow powder of the *hexahydrate*, which under the microscope was seen to consist of rhombic prisms. The salt loses all its water at 300°–400° and becomes brick-red ; and at a higher temp. it becomes dark silver-grey .and loses oxygen. J. Zehenter obtained the *decahydrate* by boiling for some hours a 1 per cent. soln. of potassium uranyl acetate. The yellow crystalline powder loses 5 mols. of water at 110°, and the remainder between 300° and dull redness. It is very sparingly soluble or insoluble in hot and cold water, alkali-lye, alcohol, and ether, and freely soluble in hot acetic acid and in dil. hydrochloric, sulphuric, and nitric acids.

J. Zehenter[6] prepared **barium heptauranate,** $Ba_2U_7O_{23}.11H_2O$, in yellow, microscopic, hexagonal leaflets, by boiling a soln. of barium uranyl acetate for 4 to 5 hrs. in a flask fitted with a reflux apparatus. The crystals lose $2\frac{1}{2}$ mols. of water at 110°, and the remainder at dull redness.

J. Zehenter prepared **lead enneauranate,** $Pb_5U_9O_{32}.10H_2O$, by boiling a soln.

of lead uranyl acetate in a flask fitted with a reflux condenser. The reddish-yellow precipitate consists of microscopic crystals. The mineral **tyuyamuyunite** is a **calcium uranatovanadate**, $CaO.2UO_3.V_2O_5.nH_2O$. It is radioactive, and, according to I. D. Kurbatoff,[7] occurs in Tyuya Muyun. V. A. Kargin prepared **uranyl vanadate**, $UO_3.2V_2O_5$, from a mixture of the hydrosols of the component oxides.

§ 14. Uranium Peroxides, and the Peruranates

Attempts by B. Drenckmann [1] to oxidize uranium to a higher oxide than the trioxide by passing chlorine into a soln. of potassium hydroxide with potassium uranate in suspension were not successful, nor did the treatment of potassium uranate with chlorous acid give any better result. A. Guyard said that when hydrated uranium trioxide or an alkali uranate is boiled with a soln. of silver nitrate, a black, insoluble crystalline powder of uranium pentoxide is formed : $4AgNO_3 + K_2U_2O_7 = Ag_2O.2UO_5 + 2AgNO_2 + 2KNO_2$; but this has not been confirmed. T. Fairley failed to prepare an oxide higher than the trioxide by treating acidic, neutral, or alkaline soln. of the uranate with hypochlorites, permanganates, or ozone ; but he found that the addition of hydrogen dioxide to a slightly acid soln. of uranyl nitrate or acetate produces a precipitate, which, after collecting, and washing successively with alcohol and ether, and drying in a desiccator, or at 100°, forms a yellowish-white, hygroscopic powder with the composition of

dihydrated **uranium tetroxide**, $UO_4.2H_2O$. A similar product was obtained by
G. Alibegoff, and L. Pissarjewsky. G. Alibegoff said that when the *dihydrate* is
heated in oxygen, it begins to decompose at 125°, and the decomposition is rapid
at 140°; it first forms uranium trioxide, and above 140°, uranosic oxide. O. Brunck
found that the salt loses no water in a current of carbon dioxide at 150°, but above
150°, water and oxygen are given off, and orange-yellow uranium trioxide is
formed—no ozone could be detected. T. Fairley found that the compound glows
below a red-heat, leaving a green uranosic oxide. A. Mazzucchelli found that the
precipitation is hindered by the presence of chlorides, sulphates, acetates, oxalates,
and tartrates owing to the tendency of the tetroxide to form soluble complex salts.
No precipitation occurs in the presence of alkalies or alkaline earths owing to the
formation of soluble peruranates. L. Pissarjewsky gave for the heat of forma-
tion $(UO_3,O) = -6.151$ Cals.; and $UO_3.H_2O+O+H_2O=UO_4.2H_2O-6.151$ Cals.
According to A. Mazzucchelli and C. Barbero, the electrolytic potentials of a soln.
of a mol of uranium trioxide in 20 litres of $N\text{-}H_2SO_4$ in the presence of the necessary
amount of hydrogen dioxide to form the tetroxide, against $N\text{-}H_2SO_4$ after 1, 3,
and 15 hrs., are with large or small platinum electrodes respectively -0.788,
-0.793, and -0.802 volt; with gold electrodes respectively -0.902, -0.893,
and -0.893 volt. The dihydrate is slightly soluble in water. A. Mazzucchelli
said that the compound precipitated by hydrogen dioxide from uranyl acetate
has a solubility of 0.0061 grm. per litre at 20°, and 0.0084 grm. per litre at 90°.
The dihydrate is soluble in a soln. of ammonium chloride. The dihydrate is
soluble in cold, and more so in warm, conc. hydrochloric acid, with the evolution
of chlorine—a mixture with conc. hydrochloric acid dissolves gold; alkali-lye
decomposes the dihydrate, with the separation of an alkali uranate and the forma-
tion of a soln. of a peruranate: $3UO_4+2K_2O=2UO_3+K_4UO_8$. In acidic liquids
the dihydrate is decomposed by hypochlorites and permanganates, with the evolu-
tion of oxygen; it does not decompose hydrogen dioxide.

T. Fairley said that if the precipitate is dried in air, it furnishes the tetra-
hydrate, $UO_4.4H_2O$, which loses half its water at 100°; but G. Alibegoff could not
prepare a tetrahydrate of definite composition. T. Fairley also reported the forma-
tion of the anhydrous tetroxide, UO_4, as a crystalline precipitate, almost white, by
adding a soln. of uranyl nitrate to a mixture of hydrogen dioxide and a large excess
of sulphuric acid, and allowing the soln. to stand for a week or more. G. Alibegoff
could not prepare the anhydrous tetroxide in this way, or by dehydrating the
dihydrate.

T. Fairley suggested $(UO_3)_2UO_6$ for the composition of the tetroxide, and he
based his opinion on the decomposition of the hydrate by alkalies—*vide infra*.
The peruranates were regarded as compounds with the composition $(R_2O)_2UO_6$,
or $R_2O.UO_3.UO_6$. L. Pissarjewsky found the ratio of uranium to active oxygen
in the tetroxide is 1 : 1, so that the formula can be written :

$$\overset{(HO)_2}{\underset{O}{\Large\diagup}}U\overset{O}{\underset{O}{\Large\diagdown}} \qquad \text{or} \qquad (HO)_4{\equiv}U\overset{O}{\underset{O}{\Large\diagdown}}$$

according to G. Alibegoff. L. Pissarjewsky represented the anhydrous oxide:

$$\overset{O}{\underset{O}{\Large\diagup}}U\overset{O}{\underset{O}{\Large\diagdown}} \qquad\qquad \overset{O}{\underset{O}{\Large\diagup}}U{=}O$$

Peruranic oxide   Uranium trioxide

G. F. Hüttig and E. von Schröder prepared the *hemienneahydrate*, $UO_4.4\frac{1}{2}H_2O$,
by dissolving 20 grms. of uranyl nitrate in water, and filtering the soln. to remove
traces of basic nitrate. The filtrate was mixed with a little 3 per cent. hydrogen
dioxide until a precipitate began to form, and continuing the precipitation by
adding a more conc. soln. of hydrogen dioxide. The sulphur-yellow precipitate
was filtered by suction and washed until the nitrate was removed. The product
was allowed to stand for 10 hrs. at room temp., and another 10 hrs. at 35° until

it was dried. The yield was about 15 grms. The dehydration curve of a mixture of this hydrate with water is shown in Fig. 11. The hemienneahydrate first appears. It can be regarded as $UO_4.5H_2O$, or $2UO_3.2H_2O_2.7H_2O$, or, by analogy with the persulphuric acids, $2H_2UO_5.7H_2O$, or **permonouranic acid.** The loss of water on a rising temp. is attended by the loss of oxygen, and at about 54° the *trihydrate*, $UO_{3.5}.3H_2O$, appears. It can be regarded as $2UO_3.H_2O_2.5H_2O$, or, by analogy with the persulphuric acids, as $H_2U_2O_8.5H_2O$, or **per-diuranic acid.** As the temp. rises to 163°, more oxygen and water are given off, and the hemihydrated trioxide appears—*vide* Fig. 11. These observations give no support to the hypothesis that a definite tetroxide exists. On the other hand, A. Rosenheim and H. Daehr prepared the amorphous salt by adding, drop by drop, a 30 per cent. soln. of hydrogen dioxide to a 10 per cent., boiling soln. of uranyl nitrate. The amorphous precipitate, washed with boiling water and dried in air, corresponded with the trihydrate, but

FIG. 11.—Dehydration Curve of Hydrated Uranium Tetroxide.

when dried to constant weight at 100°, it furnished the *dihydrate*, $UO_4.2H_2O$. By using a 2 per cent. soln. of uranyl oxalate and ammonium uranyl oxalate and a 30 per cent. soln. of hydrogen dioxide, yellowish-white crystals of the trihydrate were formed, and when these were dried at 100°, the dihydrate was produced.

P. G. Melikoff and L. Pissarjewsky showed that the alkali peruranates can be resolved by aluminium hydroxide into alkali peroxides and uranium tetroxide—*vide infra.* This reaction favours the assumption that the alkali peruranates are constituted $(R_2O_2)_2UO_4$, or $(R_2O_2)UO_4$; and this is also in agreement with the fact that while carbon dioxide has no action on uranic acid, it converts insoluble peruranates into the metal hydrocarbonate, hydrogen dioxide, and free peruranic acid. Alkali-lye partially reduces the peroxide to the trioxide and an alkali peroxide is formed. This again is in agreement with the assumption that the alkali peruranates are not salts of a peruranic acid, but rather additive compounds of the tetroxide with the metal peroxides. L. Pissarjewsky measured the electrical conductivity of soln. of peruranic acid, and also measured the catalysis of soln. of hydrogen dioxide by this acid. From this he inferred that the sodium salt Na_4UO_8, or $(Na_2O_2)_2UO_4$, is the salt of a weak **peruranic acid** with the constitution $UO(HO_2)_3.OH$, or $H_4(O_2)_3UO_2$. R. Sieverts and E. L. Müller discussed the formation of peruranic acid by the action of hydrogen dioxide on soln. of uranyl nitrate, and uranic acid.

T. Fairley, and P. G. Melikoff and L. Pissarjewsky prepared **ammonium perdiuranate,** $\{(NH_4)_2O_2\}(UO_4)_2.8H_2O$, by adding hydrogen dioxide and an excess of ammonia to a soln. of uranyl nitrate, and precipitating the salt with alcohol. The orange-yellow crystalline product can be dried in vacuo; it is less decomposable than the sodium or potassium salts. The dry salt glows like tinder when heated, forming a mixture of uranium trioxide with a lower oxide. The salt is freely soluble in water, and the aq. soln. gives precipitates with most metallic salt soln. Nearly all the salts of this type give off ozonized oxygen when treated with conc. sulphuric acid. Alkali-lye forms a precipitate of alkali uranate and a soln. of alkali peruranate. A. Mazzucchelli and C. Barbero found that the potentials of soln. of a mol of the salt in 20 litres after 1, 3, and 15 hrs. with a large platinum electrode against $0.1N$-KCl are respectively -0.557, -0.530, and -0.501 volt; with a small platinum electrode, respectively, -0.540, -0.534, and -0.501 volt; and with a gold electrode, respectively, -0.529, -0.509, and -0.427 volt.

F. W. O. de Coninck fused a mixture of uranyl chloride and alkali in a current of air, and obtained red **sodium permonouranate,** Na_2UO_5; and J. Aloy obtained the *pentahydrate*, $Na_2UO_5.5H_2O$, by adding hydrogen dioxide to a soln. of uranyl nitrate, adding some alcohol to the mixture, and stirring up with sodium hydroxide free from carbonate. The precipitate gradually dissolves and a red crystalline
mass is deposited. It is washed with methyl alcohol. The compound slowly loses oxygen at ordinary temp., and rapidly at 100°. It is decomposed by water, forming an insoluble uranate; with hydrochloric acid it forms chlorine; and with nitric acid no gas is given off, and uranium oxide is formed. P. G. Melikoff and L. Pissarjewsky obtained **lithium perdiuranate,** $Li_2O_2(UO_4)_2.8H_2O$, in pale yellow, short, isotropic prisms, by the action of lithium hydroxide and hydrogen dioxide on a soln. of uranyl nitrate, followed by precipitation with alcohol. The crystals are cubic or tetragonal. It behaves towards acids and hydrated alumina like the sodium salt. The salt is unstable, and readily forms a red acid uranate. The salt, **lithium peruranate,** $(Li_2O_2)_2UO_4$, was also obtained in red crystals which give off oxygen in the desiccator. According to T. Fairley, and P. G. Melikoff and L. Pissarjewsky, **sodium peruranate,** $(Na_2O_2)_2UO_4.8H_2O$—L. Pissarjewsky gave $9H_2O$—is obtained by adding hydrogen dioxide to a soln. of uranic or peruranic acid in soda-lye, and precipitating by the addition of alcohol. O. Kassner obtained it by the action of sodium dioxide on a soln. of uranyl nitrate, and the addition of alcohol, which precipitates the salt in yellow crystals. According to T. Fairley, the salt slowly separates from the soln. without the addition of alcohol; and if only a small proportion of alkali is present, the addition of alcohol first precipitates a deep red oil, which gradually crystallizes, and which T. Fairley represented by the formula $Na_2O.UO_3.UO_6.6H_2O$, *i.e.* **sodium perdiuranate,** $Na_2O_2(UO_4)_2.6H_2O$. The perdiuranate is considered to be derived from a pyrouranic acid, thus :

$$\text{NaO.O} \diagdown \qquad \diagup \text{ONa}$$
$$\diagup\diagup\text{U—O—U}\diagdown\diagdown$$
$$\text{O} \diagup \quad \wedge \qquad \wedge \quad \diagdown \text{O}$$
$$\text{O.O} \qquad \text{O.O}$$

The salt was also prepared by O. Kassner. According to T. Fairley, the golden-yellow needles and plates of $(Na_2O_2)_2UO_4.8H_2O$ are slowly decomposed on exposure to air—absorbing carbon dioxide and giving off oxygen. The crystals are isotropic, belonging to the cubic system. According to T. Fairley, a mol of the salt loses three gram-atoms of oxygen and three-fourths of its water when heated. It is soluble in water and sparingly soluble in alcohol. When treated with normal sulphuric acid, L. Pissarjewsky symbolized the reaction : $(Na_2O_2)_2UO_4+3H_2SO_4$ $=2Na_2SO_4+UO_2SO_4+3H_2O+3O+36.5$ Cals. Dil. sulphuric acid, hydrochloric acid, acetic acid, and succinic acid split off hydrogen dioxide. T. Fairley said that in the presence of hydrochloric acid gold is dissolved, indicating that chlorine has been liberated ; an acidified soln. of potassium permanganate, sodium hypochlorite, or other unstable oxidizing agent liberates 3 gram-atoms of oxygen. The aq. soln. is completely decomposed by boiling ; and when boiled with aq. ammonia, tabular crystals separate out. P. G. Melikoff and L. Pissarjewsky found that when a soln. of the sodium salt is repeatedly shaken up with hydrated alumina, until the filtrate contains no more hydrogen dioxide, the filtrate contains two-thirds of the quantity of hydrogen dioxide which would have been formed by the action of sulphuric acid, and peruranic acid is simultaneously formed as a precipitate containing one-third the proportion of hydrogen dioxide just indicated. The filtrate contains sodium aluminate. Hence, hydrated alumina has broken the peruranate down into sodium dioxide and uranium tetroxide. This agrees with the formula indicated above :

$$\begin{array}{c}(\text{NaO.O})_2 \diagdown \\ (\text{NaO})_2 \diagup\end{array}\text{U}\diagup\diagup\text{O}{\diagdown}\dot{\text{O}}$$
although they prefer the less likely formula $(NaO.O)(NaO)UO < O_2.Na_2O_2$. From conductivity measurements, L. Pissarjewsky inferred that the salt is strongly hydrolyzed in soln. to form hydrogen dioxide and sodium hydroxide. The soln. of one-fourth of a mol of Na_4UO_8 in v litres has the conductivity :

v	.	8	16	32	64	128	256	512	1024
λ	.	76.26	91.95	111.16	132.92	148.05	151.12	150.21	149.49

As in the case of the sodium salt, F. W. O. de Coninck prepared **potassium per-monouranate,** K_2UO_5; and J. Aloy, by a process analogous to that used for $Na_2UO_5.5H_2O$, obtained the *trihydrate,* $K_2UO_5.3H_2O$, with properties similar to those of the sodium salt. T. Fairley prepared **potassium peruranate,** $(K_2O_2)_2UO_4.10H_2O$, by adding hydrogen dioxide to a soln. of uranic or peruranic acid in potash-lye, and precipitating the salt by alcohol. The orange-yellow salt is less stable than the corresponding sodium or ammonium salt. Its properties are similar to those of the sodium salt. P. G. Melikoff and L. Pissarjewsky found that when a soln. of the sodium salt is treated with a soln. of copper sulphate, **copper peruranate,** $(CuO_2)_2UO_4.nH_2O$, is precipitated as a dark green gelatinous mass; calcium chloride similarly furnishes **calcium peruranate,** $(CaO_2)_2.UO_4.10H_2O$, in rhombic crystals; and with barium chloride, **barium peruranate,** $(BaO_2)_2UO_4.8H_2O$, is formed as an orange-coloured crystalline powder. If a suspension of the barium salt in water be treated with carbon dioxide, hydrogen dioxide and barium hydro-carbonate are formed and free peruranic acid, which with carbon dioxide is slightly decomposed into hydrogen dioxide, etc. The decomposition is attended by a sharp colour change from orange to yellow. Sulphuric acid also forms hydrogen dioxide. If barium chloride be added to a soln. of the ammonium salt, **barium perdiuranate,** $BaO_2(UO_4)_2.9H_2O$, is formed in yellow isotropic crystals; carbon dioxide furnishes two-thirds the proportion of hydrogen dioxide obtained by the action of sulphuric acid. F. W. O. de Coninck reported **barium permonouranate,** $BaUO_4$, to be formed as in the analogous case of the potassium salt; and similarly with **calcium per-monouranate,** $CaUO_4$. P. G. Melikoff and L. Pissarjewsky obtained lead uranato-peruranate, $PbUO_4.(PbO)_2UO_4$, from soln. of sodium peruranate and lead acetate. The reaction here is different from those previously considered; and this constitu-tion is inferred from the action of dil. acetic acid, which forms lead acetate and peruranic acid but no hydrogen dioxide. The dark orange-yellow product consists of isotropic crystals—cubic or tetragonal. With sulphuric acid, hydrogen dioxide is formed; with the dioxides of lead, manganese, cobalt, and nickel, there is a turbulent evolution of oxygen; and with barium and cadmium dioxides, oxygen is given off after long standing. As in the case of the copper salt, when a soln. of nickel sulphate is added to one of the sodium salt, a greenish-yellow gelatinous precipitate of **nickel peruranate,** $(NiO)_2UO_4$, is formed.

§ 15. Uranium Fluorides and Oxyfluorides

F. Giolitti and G. Agamennone [1] are reported to have said that on adding an excess of hydrofluoric acid to the liquid obtained by the electrolysis of an aq. soln. of uranyl chloride acidified with hydrochloric acid, a green precipitate of **uranium difluoride,** $UF_2.2H_2O$, is formed. A. Sieverts pointed out that this conclusion is really based on a misprint in the analysis; the actual product was $UO_2F_2.2H_2O$—*vide infra.*

H. Moissan observed that when uranium is acted on by fluorine, the chief product is **uranium tetrafluoride,** or **uranous fluoride,** UF_4. H. C. Bolton obtained it by the action of hydrofluoric acid on hydrated uranium dioxide ; and H. Hermann, by the action of that acid on uranium dioxide. H. C. Bolton also said that it can be prepared by the action of dil. hydrofluoric acid on green uranosic oxide, when a green precipitate of the tetrafluoride and a yellow soln. of uranyl fluoride are produced; this corresponds with the equation: $U_3O_8 + 8HF = UF_4 + 2UO_2F_2 + 4H_2O$. A. Ditte, on the contrary, said that the tetrafluoride, or rather a hexafluoride, remains in soln. and the green powder is uranyl fluoride ; he represented the reaction : $U_3O_8 + 18HF = 2(UF_6.2HF) + UO_2F_2 + 6H_2O + H_2$. A. Smithells noted that considerable heat is evolved during the reaction, and found that A. Ditte's statement is doubly wrong, for (i) the yellow soln. contains uranyl fluoride, as indicated by H. C. Bolton, and (ii) no hydrogen is liberated during the reaction. Some uranium oxydifluoride is also formed—*vide infra*. H. C. Bolton also found that the tetrafluoride is produced when a soln. of uranyl fluoride is reduced with stannous chloride. According to O. Ruff and A. Heinzelmann, fluorine reacts with uranium pentachloride at $-40°$ in accord with the equation : $2UCl_5 + 5F_2 = UF_4 + UF_6 + 5Cl_2$. The two fluorides can be separated by fractional distillation. When uranium carbide is treated with fluorine, only the tetrafluoride is formed. H. C. Bolton said that the *monohydrate*, $UF_4.H_2O$, is obtained as a green powder when hydrofluoric acid is added to an aq. soln. of uranium tetrachloride and the green voluminous precipitate is dried in vacuo or at $100°$. H. C. Bolton described the tetrafluoride as a green amorphous powder. O. Ruff and A. Heinzelmann said that when heated out of contact with air, it melts at about $1000°$. According to H. C. Bolton, the tetrafluoride is attacked by dry hydrogen at a red-heat, giving off hydrogen fluoride and leaving a reddish-brown residue which is insoluble in water and is scarcely attacked by acids. It has been suggested that this residue is a *subfluoride*, but this is a mere guess. The tetrafluoride is unstable ; it oxidizes in air at ordinary temp., and when warmed in air it is converted into uranyl fluoride ; at a higher temp. it passes into uranosic oxide without melting. H. Hermann found that the tetrafluoride is insoluble in water ; it is very slightly soluble in dil. acids. When heated with sulphuric acid, the hydrogen fluoride is expelled ; and it is easily and vigorously attacked by hot, conc. nitric acid. N. A. Orloff found that a soln. of uranium tetrafluoride in oxalic acid furnishes a dark green liquid with a violet fluorescence, and it deposits a complex *ammonium uranous oxalatofluoride*, $UF_4.2(NH_4)_2C_2O_4.4H_2O$. The low solubility of the tetrafluoride suggested to F. Giolitti a method of determining uranium by converting its salts into the quadrivalent stage, and then precipitating with hydrofluoric acid. H. C. Bolton added that boiling alkali-lye converts the tetrafluoride into uranous hydroxide.

H. C. Bolton found that while a soln. of formic or oxalic acid produces no precipitate in a soln. of potassium uranyl fluoride, if the acidified soln. be placed in direct sunlight, a green precipitate gradually falls, and if the action be prolonged, the soln. becomes colourless and retains only a trace of uranium. When the precipitate is washed, and dried at $100°$, it forms a green, impalpable powder of **potassium uranous pentafluoride,** KUF_5, or $UF_4.KF$. If heated in air, the salt fuses, gives off hydrogen fluoride, and leaves a residue of potassium uranate ; but if heated in a closed tube, the salt fuses, gives off hydrogen fluoride, and leaves a black residue of uranium dioxide suspended in fused potassium fluoride. It is decomposed when heated in hydrogen. The salt is quite insoluble in water and dil. acids ; it dissolves with difficulty in boiling, conc. hydrochloric acid ; but it is more easily decomposed by conc. sulphuric acid, which drives out hydrogen fluoride, forming a green soln. of uranyl sulphate. When heated with a soln. of alkali-lye, it forms a black precipitate of uranium dioxide and alkali fluoride passes into soln. A. Smithells observed that when potassium hydrofluoride and green uranosic oxide are fused together, the hydrofluoric acid of the acid salt is liberated, and acts on the oxide producing uranous fluoride, UF_4, and β-uranium oxyfluoride, UO_2F_2. In

the early stages of the fusion, the former unites with potassium fluoride to form the double salt $UF_4.KF$, whilst one molecule of UO_2F_2 and three of KF form the uranyl fluoride. By further heating, the uranous fluoride is converted into the uranyl fluoride, whilst the result of prolonged fusion of the latter is the insoluble crystalline compound, which is also obtained by using the normal instead of the acid potassium salt, and which contains no fluorine—*vide infra*, A. Ditte's sodium and potassium uranyl hexafluorides. H. C. Bolton prepared **sodium uranous pentafluoride** in a manner similar to that employed for the corresponding potassium salt. It resembles the potassium salt, but is rather more soluble, since the soln. is green, not colourless after a long exposure. The salt was not analyzed.

F. Giolitti and G. Agamennone found that if an aq. soln. of uranyl formate is exposed to sunlight for a couple of days, the soln. becomes green, and when it is treated with hydrofluoric acid, a bluish-green powder of **uranium oxydifluoride,** $UOF_2.2H_2O$, is formed. The same salt was produced by the electrolytic reduction of a soln. of uranium trioxide in an excess of hydrofluoric acid. The action of hydrofluoric acid on uranosic oxide proceeds in accord with $U_3O_8+6HF=UOF_2+2UO_2F_2+3H_2O$—*vide supra*. The uranous oxyfluoride separates as a fine green powder, whilst the uranyl fluoride remaining in soln. separates as a yellow mass on evaporation. A heavy green powder, presumably uranium tetrafluoride, is also deposited. Green **ammonium uranium oxytrifluoride,** $NH_4F.UOF_2$, was obtained by electrolyzing a soln. of ammonium uranyl carbonate in an excess of hydrofluoric acid. When the green product is heated, ammonium fluoride is given off.

O. Ruff and A. Heinzelmann prepared **uranium hexafluoride,** UF_6, in three ways. As indicated above, fluorine reacts with uranium pentachloride at $-40°$, forming the tetra- and hexa-fluorides. The hexafluoride is distilled off, and chlorine and silicon tetrafluoride which may be present are removed by the passage of a rapid current of air. The hexafluoride is also produced by the action of dry hydrogen fluoride on uranium pentachloride, whereby a complex $UF_5.nHF$ is formed, which breaks up on distillation into uranium tetra- and hexafluorides. It is difficult to separate the hydrogen fluoride from uranium hexafluoride, so that this process is not so useful. Uranium carbide with fluorine alone furnishes uranium tetrafluoride, but in the presence of chlorine, at $-70°$, the hexafluoride is produced. Uranium hexafluoride forms glistening, colourless or pale yellow, hygroscopic, monoclinic **crystals of specific gravity** 4·68 at 20·7°, and **molecular volume** 75·4. The **vapour density** at 448° is 11·7 when the calculated value for the mol. wt. $UF_6=352·8$ is 12·16, so that the vapour consists of single molecules. N. V. Sidgwick discussed the electronic structure. O. Ruff and A. Heinzelmann found that the **melting point** of the hexafluoride is 69·2°, at which temp. the vap. press. is about 2 atm. The compound sublimes without melting, at room temp. and under a diminished press. The **vapour pressure** at 0° is 48 mm.; at 20°, 129 mm.; at 37°, 298·2 mm.; at 41°, 406·1 mm.; at 45°, 410·1 mm.; at 48°, 521·2 mm.; and at 56·2°, 764·6 mm. R. Lorenz and W. Herz made observations on this subject. O. Ruff and A. Heinzelmann found that the **boiling point** is 56·2°; and the calculated mean latent **heat of vaporization** between 42° and 57° is 29·4 cals. per gram of the hexafluoride, or 10,360 cals. per mol. The salt is very hygroscopic, and it fumes in air. It is reduced to the tetrafluoride by **hydrogen** at ordinary temp. Dry **air,** and **oxygen** have no action. The hexafluoride reacts vigorously with **water,** forming a yellowish-green soln., which with ammonia forms ammonium fluoride and uranate. Uranium hexafluoride does not react chemically with **chlorine** or **bromine,** but liquid chlorine and liquid bromine dissolve some of the hexafluoride; **iodine** has no action. The hexafluoride reacts with **sulphur,** forming uranium disulphide and tetrafluoride and a gaseous sulphur fluoride. The hexafluoride is easily soluble in dil. **sulphuric acid ;** and it is almost insoluble in dry **carbon disulphide,** but there is a slow reaction, attended by the formation of the tetrafluoride; the reaction with moist carbon disulphide is vigorous, and a gas, smelling like sulphur monochloride, is given off. The hexafluoride does not react with **nitrogen ;** gaseous **ammonia** colours green the soln. in

tetrachloroethane—a substance containing ammonia, fluorine, and quadrivalent uranium is formed ; the soln. in tetrachloroethane is coloured bluish-green by **nitric oxide;** it is decomposed by **nitric acid;** it is reduced by **phosphorus** in the cold, and by **arsenic** when warmed, forming uranium tetrafluoride and phosphorus pentafluoride or arsenic trifluoride respectively. A soln. of the salt in tetrachloroethane gives a rose-coloured precipitate with **arsenic trichloride,** soluble in excess. Amorphous .**carbon** also reduces the hexafluoride to the tetrafluoride ; **carbon dioxide** has no action, and so also with **carbon monoxide.** The hexafluoride reacts slowly with **chloroform,** with **nitrobenzene,** and vigorously with **alcohol,** and with **ether,** forming hydrogen and uranyl fluorides ; and with **benzene, toluene,** or **xylene** it reacts with a hissing noise, forming hydrogen fluoride, with the separation of carbon—the resulting reduced uranium salt which is formed gives off hydrogen when treated with acids. Symmetrical **tetrachloroethane** is the best solvent. The hexafluoride is insoluble in **paraffin** oil, but reacts slowly, with the separation of carbon ; it is slowly reduced to the tetrafluoride when warmed with **silicon,** and silicon tetra-fluoride is formed ; it attacks **glass** if traces of moisture are present, forming silicon tetrafluoride. The hexafluoride at ordinary temp. forms a white crust on **sodium,** and if warmed, the reaction is attended by incandescence ; **copper,** and **silver** are feebly attacked if warmed ; **gold** is not attacked, cold or warm ; **zinc, mercury, aluminium, tin, lead,** and **iron** lose their lustre at ordinary temp., and are strongly attacked if warm ; and **platinum** is not attacked, cold or warm.

As indicated above, there are discrepancies in the conclusions of different workers on the action of hydrofluoric acid on uranosic oxide. A. Ditte said that with an excess of the conc. acid, the action is slow at ordinary temp., and rapid at 50°. The yellow soln. is said to deposit yellow crystals of **uranium dihydroctofluoride,** $UF_6.2HF$, which melt when heated in a closed platinum crucible, slowly giving off hydrogen fluoride ; if air has access, uranium dioxide and undecomposed uranium hexafluoride are formed. Hydrogen dioxide has no action. A. Smithells did not confirm A. Ditte's observation. O. Ruff and A. Heinzelmann said that a complex $UF_5.nHF$ is formed by the action of dry hydrogen fluoride on uranium pentachloride.

J. J. Berzelius found that when the yellow soln. of úranium trioxide in hydro-fluoric acid is evaporated, it furnishes a white, amorphous, pulverulent crust, which creeps up the sides of the containing vessel. The dried product dissolves readily in water, and in alcohol. H. C. Bolton showed that the product is hydrated **uranyl fluoride,** $UO_2F_2.nH_2O$, which when reduced with tin and hydrochloric acid furnishes uranium tetrafluoride. As indicated above, uranyl fluoride is one product of the action of hydrofluoric acid on uranosic oxide, and as shown by A. Smithells, and F. Giolitti and G. Agamennone, it is obtained by evaporating the filtered soln. A. Ditte also prepared it by the action of hot, conc. hydrofluoric acid on uranium dioxide. A. von Unruh also obtained it by repeatedly evaporating on a water-bath a soln. of uranyl acetate with hydrofluoric acid. W. S. Andrews obtained a fluorescent uranyl fluoride by mixing soln. of 50 grms. uranyl nitrate in 200 c.c. of water, and 75 grms. ammonium fluoride in 110 c.c. of water. The precipitate can be washed with cold water, but it is soluble in water. It is brightly fluorescent under the ultra-violet rays from an iron spark, and it is weakly responsive to excitation by X-rays. F. Giolitti and G. Agamennone could not obtain uranyl fluoride by calcining uranous oxyfluoride, $UOF_2.2H_2O$. A. Smithells obtained a white crystalline sublimate by rapidly heating uranium tetrafluoride in a closed platinum crucible and cooling after five minutes. He called the product a-uranyl fluoride to distinguish it from the yellow hygroscopic crystalline plates which he called β-uranyl fluoride obtained by evaporating the filtered soln. of uranosic oxide in hydrofluoric acid in vacuo over sulphuric acid and calcium oxide. The analyses of A. Ditte, and A. Smithells agree with the formula UO_2F_2 ; and F. Giolitti and G. Agamennone represented the product obtained on evaporating the hydrofluoric acid soln. as a *dihydrate,* $UO_2F_2.2H_2O$—*vide supra,* dihydrated uranium difluoride. Both forms produce a yellow soln. with water ; give the complex salt $3KF.UO_2F_2$

when treated with potassium fluoride ; and form uranosic oxide when calcined in air. A. von Unruh said that uranyl fluoride is insoluble in ether, and amyl alcohol. He also found that liquid ammonia acts on uranyl fluoride, forming a deep orange-red powder of **uranyl tetramminodifluoride,** $UO_2.F_2.4NH_3$, which is more stable than the corresponding chloride or bromide. Gaseous ammonia acts on uranyl fluoride to form **uranyl triamminodifluoride,** $UO_2F_2.3NH_3$, as an orange-yellow powder. When either of these ammines is warmed, it forms yellow **uranyl diammino-difluoride,** $UO_2F_2.2NH_3$. F. Olsson studied complex fluorides with organic bases.

A. Ditte said that if uranyl fluoride is heated to bright redness in a closed platinum crucible the white sublimate is **uranium oxytetrafluoride,** UOF_4. It forms a snow-white mass of acicular crystals. It melts at a red-heat, and volatilizes. When heated in air it forms uranium dioxide ; and it gives a yellow soln. with water. A. Smithells found that A. Ditte's uranium oxytetrafluoride does not exist ; it is identical with white or α-uranyl fluoride. A. Ditte reported that when uranosic oxide is fused with alkali fluorides a series of insoluble alkali uranyl hexafluorides, $4RF.UO_2F_2$, is formed, but, as indicated below, A. Smithells observed that the products are ordinary alkali diuranates. A. Ditte also said that if uranosic oxide be fused with potassium hydrofluoride, instead of potassium fluoride, the product is different. He said that if, as soon as the mass is just fused, it be allowed to cool, it appears of a bright green colour, and on treatment with water gives a yellow soln. and an insoluble green powder resembling uranous fluoride. If, however, the fusion of the mass be continued, the green colour is gradually changed to a pale yellow, and at this stage treatment with water effects almost complete soln. On still further heating, the colour becomes tinged with orange, until finally, after prolonged fusion, the crucible contains the crystalline compound $4KF.UO_2F_2$. The yellow soln. obtained by lixiviating the fused masses, freed from insoluble substances by filtration, were left at rest after being slightly conc., or were evaporated on a water-bath. In both cases small but very well-defined transparent crystals were obtained. These crystals were said by A. Ditte to be **potassium uranium oxyoctofluoride,** $4KF.UOF_4.nH_2O$, where n is either $1\frac{1}{2}$ or 3, according to the temp. at which they are deposited. A. Smithells showed that the crystals are potassium uranyl pentafluoride, $3KF.UO_2F_2$, described below. A. Ditte added that by adding potash-lye to the yellow soln. obtained by treating uranosic oxide with hydrofluoric acid the same products are obtained, and that by dissolving them in water containing potassium hydrofluoride, and recrystallizing them at 50° to 60°, a monohydrate, $4KF.UOF_4.H_2O$, is produced. These statements do not agree with the observations of J. J. Berzelius, and H. C. Bolton ; and A. Smithells showed that (i) the yellow soln. obtained by acting on uranosic oxide with hydrofluoric acid is uranyl fluoride ; (ii) that when an excess of hydro-fluoric acid is present and potassium hydroxide is added, potassium uranyl pentafluoride, indicated below, is formed ; and (iii) when this salt is dissolved in water containing not more than 13 per cent. of potassium hydrofluoride, triclinic potassium diuranyl ennea-fluoride is formed. Similar remarks probably apply to A. Ditte's **rubidium uranium oxyoctofluoride,** $4RbF.UOF_4.6H_2O$, prepared like the potassium salt.

J. J. Berzelius showed that uranyl fluoride forms yellow, soluble, crystalline compounds with the alkali fluorides. H. C. Bolton prepared **ammonium uranyl pentafluoride,** $(NH_4)_3UO_2F_5$, by evaporating a soln. of ammonium uranate in hydro-fluoric acid over conc. sulphuric acid. H. Bürger used ammonium diuranate. H. Baker prepared the salt by adding ammonium fluoride to a soln. of uranyl nitrate, when the salt is precipitated in tetragonal crystals, probably isomorphous with the corresponding potassium salt, and of sp. gr. 3·186 at 20°. H. C. Bolton said that the salt is freely soluble in water, and according to H. Bürger, 100 grms. of a sat. soln. at 27° has 10·11 grms. of the salt ; and 20·70 grms. at 81·3°. A. Miolati and U. Alvisi found that the electrical conductivity, λ, of soln. of one-third of a mol, $(NH_4)_3UO_2F_5$, in v litres of water, is as follows :

v .	32	64	128	256	512	1024	∞
λ .	96·99	104·00	109·6	115·6	119·3	126·1	133·1

The difference in the electrolytic conductivities $\lambda_{1024}-\lambda_{32}=29\cdot1$, and $\mu_\infty=133\cdot1$ indicates that stable complexes are formed : $(NH_4)_3UO_2F_5 \rightleftharpoons 3NH_4^{\cdot}+(UO_2F_5)'''$. H. C. Bolton said that the salt is less soluble in hydrofluoric acid than in water, and insoluble in alcohol. When heated out of contact with air, ammonium fluoride is volatilized ; and when exposed to air, green uranosic oxide is formed.

According to H. C. Bolton, potassium fluoride causes in a soln. of uranium nitrate

a heavy crystalline lemon-yellow precipitate, which, by washing with cold water and recrystallization from hot water, can be obtained pure. It is well in the preparation of this salt to add an excess of potassium fluoride, as the salt is soluble in uranium nitrate. H. Baker added that by crystallizing the salt thus prepared from pure water or from a soln. of acid potassium fluoride (containing not more than 13 per cent.), tabular triclinic crystals are always formed. But by crystallization from a nearly sat. soln. of potassium hydrofluoride, a salt separates in minute tetragonal crystals. Furthermore, by adding potassium fluoride to a soln. of uranium nitrate in quantity insufficient to produce a permanent precipitate, or by recrystallizing either of the preceding salts from water containing a little uranium nitrate, monoclinic crystals are obtained : so that three distinct potassium uranyl oxyfluorides exist. H. C. Bolton, and H. Baker obtained the tetragonal **potassium uranyl pentafluoride,** $3KO.UO_2F_2$, as indicated above ; also by adding potassium fluoride to a soln. of freshly-precipitated potassium diuranate in hydrofluoric acid ; and by the crystallization of a mixed soln. of potassium fluoride and uranyl fluoride. A. Smithells obtained it by evaporating a soln. of potassium fluoride or hydrofluoride and uranyl fluoride, and by fusing potassium hydrofluoride with uranosic oxide—*vide supra.* H. C. Bolton tried unsuccessfully to prepare this salt by heating to redness for more than an hour a mixture of potassium uranyl sulphate with sodium fluoride and sulphate as a flux. The greater part of the potassium uranyl sulphate remained unchanged, with the exception of a little sodium uranate which was formed near the surface of the mass. Potassium uranyl pentafluoride is dimorphous. H. C. Bolton described (i) the yellow, tabular crystals which he prepared by cooling hot, conc. soln. and which are monoclinic prisms with the axial ratios $a : b : c$ $=1·375 : 1 : 3·477$, and $\beta=99°$ 40′ ; and he also obtained (ii) twinned tetragonal crystals, with the axial ratio $a : c=1 : 2·0815$, by the spontaneous evaporation of a cold soln. H. Baker gave $a : c=0·992$, and found penetration twinning and trilling. The sp. gr. of the tetragonal form is 4·263. The crystals are only slightly fluorescent. H. C. Bolton observed that when the salt is heated in a closed vessel, it melts to a red liquid which freezes to a yellow mass ; if heated while exposed to air, fluorine is given off, and potassium diuranate is formed. A. Miolati and U. Alvisi found that the electrical conductivity, λ, of soln. of one-third of a mol of $K_3UO_2F_5$, in v litres is as follows :

v .	32	64	128	256	512	1024	∞
λ .	97·67	104·8	109·6	115·1	119·2	127·3	133

The difference in the electrical conductivities of soln. of the salt $\lambda_{1024}-\lambda_{32}=29·6$ corresponds with that of a tribasic uranylfluoric acid : $K_3UO_2F_5 \rightleftharpoons 3K^{\cdot}+(UO_2F_5)'''$. H. C. Bolton observed that when the salt is heated in dry hydrogen, it forms uranium tetrafluoride, uranium dioxide, and potassium fluoride. At 21°, 100 parts of water dissolve 12·5 parts of the salt. The aq. soln. reddens litmus and is not decomposed by boiling, and H. Baker added that the solubility of the salt in a soln. of potassium hydrofluoride is less than in water, and the original salt can be crystallized from its soln. in this menstruum—*vide infra.* H. C. Bolton found that the salt is completely decomposed by warm, conc. sulphuric acid. When ammonia is added to the aq. soln., a precipitate of ammonium diuranate is formed ; barium chloride gives a voluminous white precipitate ; lead acetate, an orange-yellow precipitate, very soluble in acids ; and calcium chloride, a white precipitate difficult to filter. Oxalic or formic acid and a soln. of this salt, when exposed to sunlight, form potassium uranous pentafluoride. A soln. of potassium uranyl pentafluoride gives no precipitate with salts of copper, silver, zinc, mercury, iron, or platinum ; and ammonium or sodium carbonate does not decompose the boiling soln. When the pentafluoride is fused with sodium carbonate there are formed sodium uranate and fluoride. The salt is insoluble in alcohol, and ether ; and alcohol added to an aq. soln. precipitates the salt. As indicated above, a soln. of potassium uranyl pentafluoride gives a precipitate with barium chloride, which, when washed, and dried at 100°,

forms orange-yellow **barium uranyl pentafluoride,** $Ba_3(UO_2F_5)_2.2H_2O$. It gives off water and hydrogen fluoride without melting when heated out of contact with air; it is very sparingly soluble in hot water; it is freely soluble in acids, and the soln. precipitates barium sulphate when treated with sulphuric acid, and ammonium uranate when treated with ammonia. The corresponding **calcium uranyl penta-fluoride,** $Ca_3(UO_2F_5)_2.nH_2O$, and **lead uranyl pentafluoride,** $Pb_3(UO_2F_5)_2.nH_2O$, appear to be produced in an analogous manner—*vide supra.*

H. Baker found that when potassium uranyl pentafluoride is crystallized from water, or from a soln. containing not more than 13 per cent. of potassium hydro-fluoride, six-sided plates—rarely prisms—of **potassium diuranyl enneafluoride,** $K_5(UO_2)_2F_9$, are formed. The triclinic crystals have the axial ratios $a:b:c$ $=0·6222:1:0·568$, and $a=72°\ 38'$; $\beta=116°\ 23'$, and $\gamma=111°\ 57'$. The sp. gr. is 4·379 at 20°. The crystals are markedly fluorescent; and they can be recrystallized unchanged from water. The zirconium salt $Na_5Zr_2F_{13}$ is analogous. H. Baker obtained **potassium diuranyl heptafluoride,** $K_3(UO_2)_2F_7$, from a soln. of uranyl fluoride mixed with insufficient potassium fluoride to form a precipitate; and by recrystallizing either of the preceding potassium salts from a soln. containing uranyl fluoride. The monoclinic prisms have the axial ratios $a:b:c$ $=0·918:1:0·978$, and $\beta=114°\ 0'$. The sp. gr. is 4·108 at 20°. The green fluor-escence is very marked. The salt separates unchanged from its soln. in hot water.

H. C. Bolton evaporated in a desiccator, over sulphuric acid, a soln. of uranyl nitrate and sodium fluoride, or a soln. of sodium uranate in hydrofluoric acid, and obtained tabular or prismatic crystals of **sodium uranyl trifluoride,** $Na(UO_2)F_3$. $4H_2O$. The monoclinic crystals have the axial ratios $a:b:c=1·0270:1:0·5222$, and $\beta=94°\ 51'$. The crystals lose half their water at 100°; they melt when heated, forming sodium diuranate. The salt is not so stable as the potassium salts, but behaves similarly. When the aq. soln. is heated, or when an attempt is made to recrystallize the salt from its aq. soln., sodium fluoride crystallizes out separately.

A. Ditte described **potassium uranyl hexafluoride,** $K_4(UO_2)F_6$, as a result of fusing uranosic oxide with potassium fluoride mixed with a little carbonate, or by dissolving uranosic oxide in molten potassium hydrofluoride, and precipitating with potassium carbonate. The yellow, six-sided plates are stable in air at a red-heat; hydrogen reduces a little of the salt at a red-heat; when heated with ammonium chloride in hydrogen, uranium dioxide and potassium chloride are formed; it is insoluble in hot and cold water and soluble in acids. A. Ditte similarly obtained **rubidium uranyl hexafluoride,** $Rb_4(UO_2)F_6$; **sodium uranyl hexafluoride,** $Na_4(UO_2)F_6$; and **lithium uranyl hexafluoride,** $Li_4(UO_2)F_6$. A. Smithells showed that in all probability A. Ditte erred in some way, for the products obtained are in all cases diuranates, and not fluorides at all.

According to S. Lordkipanidze, when an aq. soln. of sodium uranyl trifluoride is treated with hydrogen dioxide, and the intense yellow soln. is evaporated on a water-bath at 60° to 70°, a yellow, granular salt, **sodium uranium peroxyfluoride,** $NaF.UO_4.5H_2O$, is formed. It loses four mols. of water at 100°. Again, if an excess of hydrogen dioxide is added to an aq. soln. of potassium uranyl pentafluoride, the intense yellow liquid deposits, after standing some time, yellow, pulverulent **potassium uranium peroxyfluoride,** $KF.UO_3F_2.3(KF.UO_4).4H_2O$.

§ 16. Uranium Chlorides

According to E. M. Péligot,[1] if uranium tetrachloride is heated, at the temp. approaching volatilization, in dry hydrogen so long as hydrogen chloride is given off, **uranium trichloride**, UCl_3, is formed. H. Löbel added that the hydrogen should be thoroughly dried and be free from all traces of oxygen. C. F. Rammelsberg obtained the trichloride by heating the tetrachloride in ammonia, but in that case, added E. Uhrlaub, the product will contain some nitride. J. L. C. Zimmermann obtained what he regarded as a soln. of the salt by reducing uranyl salts with zinc and hydrochloric acid, or, according to F. Stolba, with lead and hydrochloric acid. A. Rosenheim and H. Löbel prepared a soln. of the trichloride in a large excess of hydrochloric acid by the electrolytic reduction of a soln. of uranium trioxide in hydrochloric acid of sp. gr. 1·12, using a layer of mercury as cathode. To complete the reduction, the soln. must be cooled to 0° towards the end of the electrolysis. In the presence of traces of dissolved mercury or platinum, the reduction stops at quadrivalent uranium, due, it is supposed, to the fact that these substances facilitate the liberation of hydrogen. A. Rosenheim and H. Löbel observed that the trichloride forms dark red, hygroscopic needles. K. Someya discussed the colour of tervalent uranium ions. W. Biltz, and W. Biltz and C. Fendius gave 5·440 for the sp. gr. at 25°/4°; 83·4 for the mol. vol.; and for the heat of formation $(U,_3^2Cl_2)$ =213 Cals. E. M. Péligot found it to be freely soluble in water; and the purple soln. quickly decomposes, giving off hydrogen and forming a red deposit of uranium oxide and a green soln. of uranium tetrachloride. The aq. soln. are therefore very unstable, and A. Rosenheim and H. Löbel observed that the purple soln. in hydrochloric acid is more stable than the aq. soln., and that water and most reagents decompose the acid soln. of the trichloride. The soln. of the trichloride in acetic acid is red. J. L. C. Zimmermann measured the absorption spectrum of soln. of the trichloride.

E. M. Péligot[2] observed that uranium burns brilliantly in chlorine, forming **uranium tetrachloride**, or **uranous chloride**, UCl_4; he prepared the salt by passing dry chlorine over an intimate mixture of uranous oxide and carbon at a red-heat. The red vapours of the uranium tetrachloride condense near to the hot zone. C. F. Rammelsberg used uranosic oxide, and H. Löbel, uranium trioxide. H. E. Roscoe said that any of the oxides of uranium or uranyl chloride can be employed, and that octahedral crystals of the tetrachloride are deposited nearest to the hot zone, and farther away the pentachloride is deposited in black, needle-shaped crystals mixed with a brown powder. W. E. Schilz, C. F. Rammelsberg, H. Löbel, and A. Roderburg employed this process; whilst H. Moissan passed chlorine over red-hot uranium carbide. A. Colani observed that the production of the pentachloride is avoided if uranium dioxide be employed in place of the trioxide or of uranosic oxide; and H. E. Roscoe found that the pentachloride is converted into the tetrachloride if it be heated in a current of carbon dioxide. As shown by E. Demarçay, and L. Meyer, the metal oxides can be chlorinated by passing the vapour of carbon tetrachloride over the red-hot oxide. This process was employed by A. Colani for uranium tetrachloride. P. Camboulives passed the vapour of carbon tetrachloride over uranium trioxide at 300°; and A. Michael and A. Murphy heated a mixture of uranium dioxide and carbon tetrachloride in a sealed tube at 250°. A. Colani, C. Matignon and F. Bourion, H. Löbel, F. Bourion, D. Lely and L. Hamburger, and J. F. Goggin and co-workers prepared the tetra-chloride by heating uranosic oxide, or uranium trioxide in a current of the vapour of sulphur monochloride, alone or mixed with chlorine. A. Colani said that if the

sulphur monochloride is associated with an excess of sulphur, the reaction does not proceed so easily as in the converse case. R. W. Moore recommended the following procedure :

The uranium oxide is placed in quartz or porcelain boats inserted in a 5 cm. porcelain tube heated in an electrical resistance furnace. An empty boat is placed at one end of the porcelain tube, and re-distilled sulphur monochloride is allowed to flow into this boat drop by drop from a tube connected with a separatory funnel. The other end of the tube projecting beyond the furnace is closed by a rubber stopper with a large outlet tube opening under sulphur monochloride contained in a bottle. The furnace is inclined downwards towards the outlet end so as to allow the outflow of any sulphur monochloride condensing in the cool end of the tube. The tube is heated to 200°–300°, and the dropping-in of the sulphur monochloride is commenced. The temp. is gradually raised to 500°, and maintained there for 3 or 4 hrs. The uranium oxide is converted into a greenish, coarsely crystalline mass, which absorbs moisture slowly. The temp. is not high enough either to melt or to sublime the tetrachloride. The product is preserved in sealed tubes. Some oxide is still present and the product is purified by sublimation. A hard glass tube about 4 cms. in diameter is bent ; thus the inlet is arranged so that it can be filled with chlorine dried by bubbling through sulphur monochloride. The crude tetrachloride is placed at the lowest part of the bend ; and the outlet is closed by a stopper carrying a small tube leading to the exit. The tetrachloride is heated to bright redness while a moderate current of chlorine is passed through the tube. The dark red vapours of the tetrachloride condense in greenish crystals close to the hot zone. A fluffy yellow substance is deposited in the cooler part of the tube. It appears to be a complex of sulphur monochloride and uranium tetrachloride, because, on replacing the current of chlorine by nitrogen, and heating the part of the tube containing these crystals, they decompose into sulphur monochloride and uranium tetrachloride. The uranium tetrachloride is sealed in tubes or bottles containing dry nitrogen.

J. Aloy said that uranium tetrachloride is formed when a soln. of uranosic oxide or uranyl hydroxide in hydrochloric acid, mixed with alcohol, is exposed to sunlight and the product precipitated by adding ether. The reduction of soln. of uranyl chloride in the presence of ether, in sunlight, was first noticed by A. F. Gehlen, in 1806. R. Arndt and W. Knop also obtained a soln. of the tetrachloride by boiling for 15 mins. a soln. of uranyl chloride and hydrochloric acid with copper and a trace of hydrochloroplatinic acid. The cold soln., after filtration, was treated with hydrogen sulphide to remove copper, and the filtrate boiled to remove hydrogen sulphide. The soln. of uranium tetrachloride was treated with ammonia, and the precipitated uranous hydroxide dissolved in hydrochloric acid. J. Aloy and G. Auber, and V. Kohlschütter and H. Rossi recommended sodium hyposulphite as reducing agent.

As observed by E. M. Péligot, and H. Löbel, uranium tetrachloride forms lustrous, dark green, octahedral crystals belonging to the cubic system, when produced by sublimation in a slow current of chlorine, but, added R. Sendtner, with a fast current of chlorine the sublimate is a green, crystalline powder. H. Hansen found the X-radiogram agrees with a cubic lattice with $a=14\cdot57$ A., and 24 mols. per cube. W. E. Schilz gave 4·73 for the sp. gr. at 4°/4° ; O. Hönig-schmid and W. E. Schilz, 4·725 at 25°/4°, W. Biltz and C. Fendius, 4·854 at 25°/4°, and for the mol. vol., 78·3. J. L. C. Zimmermann observed that the vapour is red, and that the vapour density is 13·33 when the value calculated for UCl_4 is 13·21 ; and from the effect of the tetrachloride on boiling bismuth trichloride, L. Rügheimer and K. L. Gonder obtained a mol. wt. of 373, corresponding closely with 380·3 required for UCl_4. W. Biltz and C. Fendius gave for the heat of formation $(U,2Cl_2)=251$ Cals. E. Becquerel, and T. R. Merton investigated the absorption spectrum—*vide supra.* W. Hampe found that the molten chloride conducts the electric current and is at the same time electrolyzed. As indicated above, the tetrachloride is reduced to the trichloride when it is heated in hydrogen. A. Voigt and W. Biltz found the sp. electrical conductivity at 570° to be 0·34, and at 620°, 0·48. H. G. Grimm, and G. von Hevesy discussed the m.p. and electrical conductivity. E. M. Péligot noted that the crystals fume in moist air, and they are very deliquescent, forming an emerald-green soln. The salt is freely soluble

in water, dissolving with a hissing noise, the evolution of heat, and the formation of a dark emerald-green liquid. R. Arndt and W. Knop also observed that a soln. of the salt is fairly stable in the cold, but if ferrous chloride is present as impurity, the uranium is soon oxidized to the quinquevalent stage. H. Löbel said that the salt in aq. soln. is completely hydrolyzed, so that, as E. M. Péligot observed, it does not then form complex salts with alkali chlorides, but it does so in non-hydrolyzing solvents. According to E. M. Péligot, when the aq. soln. is evaporated, hydrochloric acid is given off, and there is formed a residue of hydrated uranous oxide which yields a soln. with water; and when evaporated in vacuo, there remains a deliquescent residue not uranium tetrachloride; J. J. Berzelius also observed that the boiling aq. soln. gives off hydrochloric acid, forming hydrated uranous oxide— J. Aloy said that the black precipitate formed in the boiling soln. has the composition $UCl_4.5UO_2.10H_2O$; and R. Arndt and W. Knop, that when the dark green soln. is dropped into boiling water, it is decolorized and hydrated uranous oxide is precipitated. The tetrachloride was found by H. Kunheim to be converted into uranosic oxide when heated to redness in water-vapour. H. Hermann showed that dry hydrogen sulphide transforms it into uranium disulphide and hydrogen chloride; and A. Colani added that the hydrides of the metalloids readily react with the tetrachloride with double decomposition at a red-heat; and with oxygen compounds it reacts in the dry way, forming uranium dioxide and a chloride— e.g. with tungsten trioxide, arsenic trioxide, etc. W. Peters found that the dehydrated salt absorbs dry ammonia to form **uranium triamminotetrachloride,** $UCl_4.3NH_3$, and the ammonia is retained in vacuo. C. F. Rammelsberg said that an excess of sodium thiosulphate precipitates from an aq. soln. of uranium tetrachloride a mixture of sulphur and a basic uranous sulphite, while some sulphur dioxide is given off. A. Remelé said that almost neutral soln. of uranous salts give precipitates free from uranium when treated with ammonium and sodium thiosulphates. E. Uhrlaub observed that when heated in ammonia gas, uranium nitride is formed, but C. F. Rammelsberg observed that, at ordinary temp., uranium tetrachloride absorbs 5·44 parts of ammonia gas, with the development of heat. This is a little more than is required for *uranous amminotetrachloride*, $UCl_4.NH_3$. H. Löbel observed that uranium tetrachloride forms a pale green soln. with alcohol, with partial alcoholysis. The alcoholysis is hindered by saturating the soln. with hydrogen chloride, and complex organic chlorides can be obtained with the liquid. The tetrachloride also forms pale green soln. with acetone, acetic ester, and benzoic ester; but it is insoluble in ether, chloroform, and benzene. T. R. Merton also noted that uranium tetrachloride is soluble in ethyl alcohol, acetone, acetonitrile, ethyl acetoacetate, and acetophenone. The reduction of uranyl salt soln. in the presence of many organic substances has been previously discussed. J. E. Abelous and co-workers found that the insolation for several hours of common sugars— sucrose, glucose, levulose, and lactose—in 2 per cent. soln. caused no appreciable change, but if 25 c.c. of the soln. contains 2 c.c. of a 2 per cent. soln. of a uranyl salt, the yellow soln. becomes green by exposure to a bright light—in the case of uranyl acetate, a violet precipitate is formed. Levulose and sucrose react most rapidly; aldehydes, particularly formaldehyde, are amongst the products of the reaction. Inulin is more readily attacked by this treatment than is starch or glycogen. As previously indicated, E. M. Péligot, H. Hermann, and others found that the tetrachloride is reduced to the metal by sodium, potassium, aluminium, etc.; and A. Colani observed that binary compounds with potassium, sodium, magnesium, aluminium, tin, and antimony are formed when these metals are heated with uranium tetrachloride. Complex salts with tin, titanium, and thorium tetrachlorides could not be prepared by H. Löbel. All the uranous salt soln. are strong reducing agents—e.g. soln. of gold and silver salts give precipitates of the metal, potassium permanganate soln. are rapidly decolorized, ferric salts are converted into ferrous salts, etc.—*vide supra*, analytical reactions of uranium.

J. Aloy prepared **lithium uranous hexachloride,** $2LiCl.UCl_4$, by passing the

vapour of uranium tetrachloride over the alkali chloride at a dull red-heat; the alkali salt gradually melts as the uranium tetrachloride is absorbed. Similarly with the sodium and potassium salts. These salts are pale green when first prepared, but are very hygroscopic, and rapidly darken as they absorb moisture from the air. They are very soluble in acetic acid, and dissolve also in water, with development of heat, giving a strongly acid soln. which oxidizes slowly in the air at ordinary temp., and more rapidly when heated. The soln. are decomposed by water, so that when evaporated in vacuo over sulphuric acid, crystals of alkali chloride are deposited and a green, uncrystallizable mass is left behind. Alcohol gives a green soln., which also rapidly oxidizes and becomes yellow. H. Moissan, A. Colani, and J. Aloy prepared **sodium uranous hexachloride,** $2NaCl.UCl_4$, by passing the vapour of the tetrachloride over sodium chloride at dull redness; A. Colani added that a great excess of the sodium salt is an advantage. The apple-green crystals melt at about 390°, and very little vapour is given off. The salt is very hygroscopic and decomposes like uranium tetrachloride in the presence of water, in which the salt is freely soluble. It is also decomposed by alcohol. The preparation and properties of **potassium uranous hexachloride,** $2KCl.UCl_4$, are indicated in connection with the lithium salt; and similarly with **rubidium uranous hexachloride,** Rb_2UCl_6, and **cæsium uranous hexachloride,** Cs_2UCl_6. J. Aloy prepared **calcium uranous hexachloride,** $CaCl_2.UCl_4$, by the method employed for the lithium salt, but especial care must be taken to dry the chloride before the heating, which must not be taken too far. Similarly also with **strontium uranous hexachloride,** $SrCl_2.UCl_4$, and with **barium uranous hexachloride,** $BaCl_2.UCl_4$. The complex salts with the alkaline earth metals are of a deeper green colour than those with the alkali metals; but like the latter, they are decomposed by water, and cannot be obtained crystalline by evaporating the aq. soln. in vacuo. H. Löbel also prepared complex salts with pyridine and quinoline.

H. E. Roscoe [3] prepared **uranium pentachloride,** UCl_5, simultaneously with the tetrachloride, by passing an excess of dry chlorine over a moderately heated mixture of charcoal with any of the oxides of uranium or uranyl chloride. The pentachloride exists in two distinct forms, according as it is produced slowly or quickly. When the current of chlorine is slow, the pentachloride of uranium forms long, dark, needle-shaped crystals, which reflect light with a green, metallic lustre, but appear of a ruby-red colour when viewed by transmitted light. If the rate at which the chlorine passes be rapid, the pentachloride is deposited in the form of a light, brown, mobile powder. The octahedral crystals of the tetrachloride are always deposited in quantity in that part of the tube nearest to the heated mixture; then the black, needle-shaped crystals of pentachloride are formed, mixed with more or less of the brown powder, which is generally carried for a considerable distance along the tube. According to A. Michael and A. Murphy, P. Camboulives, and F. Bourion, the pentachloride is also formed along with the tetrachloride when the uranium oxides are chlorinated by heating them in the vapour of carbon tetrachloride or sulphur monochloride. V. Pimmer employed an analogous process. O. Ruff and A. Heinzelmann recommended converting the mixture of uranium pentachloride and tetrachloride wholly into the pentachloride by sealing it with liquid chlorine in a glass tube; heating the vessel protected by an iron tube; afterwards cooling the vessel to liquefy the excess of chlorine, and then allowing the chlorine to escape by evaporation. H. E. Roscoe said that the pentachloride forms black needles and a brown powder, and added that it cannot be volatilized without partial decomposition, either when heated alone or in an atm. of chlorine or of carbon dioxide, uranium tetrachloride and free chlorine being formed. This dissociation begins in an atm. of carbon dioxide at a temp. of 120° and is completed at 235°, since the percentage of chlorine contained in the residue is four-fifths that required for the tetrachloride. The tetrachloride, when similarly heated, loses no chlorine. V. Pimmer said that the dissociation proceeds very slowly even at the ordinary temp. of a room, and volatilization occurs at 70° under 7 mm. press. The

vapour density is then about half that required for the pentachloride, showing that the compound is dissociated : $2UCl_5 \rightleftharpoons 2UCl_4 + Cl_2$. The effect of the pentachloride on the b.p. of ether agrees with a mol. wt. 248·4—when the theoretical value for UCl_5 is 415·75 ; the results with chloroform, acetic acid, and ethyl alcohol show that chemical action occurs. V. Pimmer estimated that the m.p. of the pentachloride is above 300°.

According to H. E. Roscoe, the pentachloride is extremely hygroscopic, yielding on exposure to the *air* for a few minutes a yellowish-green liquid. When thrown into *water*, the pentachloride hisses as it passes into soln., giving off fumes of hydrochloric acid. V. Pimmer said that the green soln. smells both of chlorine and of hydrochloric acid ; and if only a small proportion of water is employed, the liquid blackens, in consequence of the formation of uranous hydroxide. H. E. Roscoe observed that when the pentachloride is heated to redness in dry *ammonia*, a black nitride is formed. A. W. Cronander heated uranium trioxide in a sealed tube with an excess of *phosphorus pentachloride* for 3 or 4 days, and obtained yellowish-red **uranium phosphodecachloride,** $UCl_5.PCl_5$. The product is decomposed by water : $2(UCl_5.PCl_5) + 9H_2O = UP_2O_7 + UO_2Cl_2 + 18HCl$. V. Pimmer, and H. Löbel found that uranium pentachloride forms a green soln. with *ethyl alcohol* which becomes yellow when it is boiled. H. Löbel said that the pentachloride is insoluble in dry *ether, benzene, nitrobenzene,* and *ethylene bromide* ; sparingly soluble in *carbon tetrachloride,* and *chloroform,* forming yellow soln. ; soluble in *ethyl benzoate* and the soln. becomes brown ; and soluble in *acetone* and *trichloroacetic acid,* and the soln. becomes brown when heated. The best solvents observed were *ethyl acetate* and *benzonitrile,* but the b.p. of these solvents is lowered, not raised, by the pentachloride, showing that some chemical action has taken place. V. Pimmer's observations with soln. in ether, chloroform, acetic acid, and ethyl alcohol are indicated above. According to V. Pimmer, the green soln. in *ethyl acetate* becomes yellow when boiled ; the dark yellow soln. in *benzaldehyde* does not appear to change when boiled ; *acetone* forms a green soln. ; *glycerol* forms a green soln. at 50° ; *benzyl alcohol* dissolves traces of the salt, forming a green soln. ; *carbon disulphide* decomposes uranium pentachloride, and the smell of sulphur monochloride gradually develops without dissolution ; *nitrobenzene* dissolves traces; *benzonitrile* forms a yellow soln. ; warm *xylidine,* and *p-toluidine* dissolve some pentachloride ; whilst the pentachloride is insoluble in *benzene, aniline, ligroin, pyridine, quinoline, ethyl sulphide,* and *amyl sulphide.* H. Löbel added that many *organic oxy-compounds* dissolve the pentachloride, primarily forming addition products, which—particularly the hydroxy-compounds—rapidly decompose into uranous compounds, or pass into oxychlorides with the evolution of hydrogen chloride.

H. Löbel [4] left uranium pentachloride for many days in contact with liquid chlorine in a sealed tube, in the presence of various possible catalytic agents, but did not obtain **uranium hexachloride,** UCl_6, analogous to the hexafluoride. A. Michael and A. Murphy heated uranium trioxide or uranosic oxide with carbon tetrachloride for many hours in a sealed tube, and G. M. Ross heated uranous oxide in a sealed tube with sulphur monochloride, and obtained a green, non-volatile solid with the composition of the hexachloride. It decomposes when warmed, and with water forms uranyl chloride. The evidence for the individuality of the hexachloride is not altogether satisfactory.

§ 17. Uranium Oxychlorides

J. Aloy [1] prepared **uranous dioxytetrachloride,** $UO_2.UCl_4.H_2O$, as a pale green, soluble crystalline mass, by evaporating an aq. soln. of uranium tetrachloride at a low temp., in vacuo, dissolving the product in alcohol, adding ether to the alcoholic soln., washing the precipitate with ether, and drying it in vacuo. N. A. Orloff prepared **sodium uranous dioxyhexachloride,** $Na_2UCl_6.UO_2.6H_2O$, in greenish-yellow crystals, by evaporating an aq. soln. of uranous chloride and sodium uranate. N. A. Orloff obtained **uranous tetroxytetrachloride,** $2UO_2.UCl_4.13H_2O$, by the action of light on a soln. of uranyl chloride in 2 parts of ether and 1 part of alcohol. It forms green soln. with water and alcohol. When the *tridecahydrate* is dried over sulphuric acid it forms the *monohydrate*. If it be dried at 100°, **uranous octoxytetrachloride,** $4UO_2.UCl_4$, is formed ; it gives dark brown soln. with water, and with alcohol. J. J. Berzelius observed that if an aq. soln. of uranium tetrachloride be concentrated by heat, it furnishes a black powder ; and J. Aloy obtained in a similar way a product with the composition **uranous decoxytetrachloride,** $5UO_2.UCl_4.10H_2O$. He also obtained it by allowing uranous

hydroxide and a soln. of uranium tetrachloride in air-free water to act on one another for some days in a closed flask. The product when dried is black; and it can be kept in air a long time without becoming yellow.

According to E. M. Péligot,[2] dry chlorine unites with uranium dioxide at a red-heat to form an orange-yellow vapour, which condenses, forming yellow crystals of **uranyl chloride,** UO_2Cl_2. If the uranium dioxide contains any uranosic oxide, uranium trioxide remains behind on dissolving the compound in water. F. P. Venable and D. H. Jackson chlorinated uranosic oxide at 500° by a mixture of chlorine and carbon monoxide. A. von Unruh observed that when uranyl acetate, dissolved in amyl alcohol, is evaporated with hydrochloric acid until all the acetic acid is expelled, then 4 to 6 times with water to remove the excess of hydrochloric acid, and the soln. freed from water by boiling, there are formed green, fluorescent plates of the anhydrous salt. F. W. O. de Coninck added a soln. of barium chloride, drop by drop, to a conc., freshly prepared, aq. soln. of uranyl sulphate, filtered off the precipitated barium sulphate, and evaporated the soln. on a water-bath to obtain uranyl chloride. The early workers obtained a soln. of the salt by dissolving uranyl hydroxide in hydrochloric acid, or by oxidizing a soln. of uranium dioxide or uranosic oxide in hydrochloric acid, by means of nitric acid, or by exposure to air. According to M. H. Klaproth, the evaporation of the yellow soln. furnishes efflorescent, oblique, four-sided plates; L. R. Lecanu obtained very deliquescent needles; and J. A. Arfvedson, an uncrystallizable, deliquescent syrup. J. Aloy reported that a soln. of uranyl chloride in hydrochloric acid, saturated at 15°, furnishes crystals of **uranyl hydrotrichloride,** $UO_2Cl_2.HCl.2H_2O$, when cooled to $-10°$, and added that the crystals lose hydrogen chloride when exposed to air; but F. Mylius and R. Dietz showed that a soln. of uranium trioxide in conc. hydrochloric acid forms yellowish-green, doubly refracting, hygroscopic prisms of the *trihydrate,* $UO_2Cl_2.3H_2O$, or $H_4UO_5.2HCl$, when evaporated in a desiccator over sulphuric acid. When these crystals are heated above 100°, they give off water, hydrogen chloride, and chlorine. F. W. O. de Coninck said that if an aq. soln. of uranyl chloride be evaporated over sulphuric acid, it furnishes crystals of the *monohydrate,* $UO_2Cl_2.H_2O$, but F. Mylius and R. Dietz showed that if a sat. aq. soln. be evaporated, the syrupy liquid furnishes flattened needles of **uranyl hydroxychloride,** $HUO_3Cl.2H_2O$, or $UO_2(OH)Cl.2H_2O$, or $H_4UO_5.HCl$. This salt loses its water of crystallization at 150°, and its aq. soln. scarcely reddens blue litmus. Silver oxide precipitates the whole of the chlorine from its aq. soln., leaving a colloidal soln. of uranic acid (*q.v.*). F. W. O. de Coninck observed no evidence of the formation of $UO_2Cl(OH)$ in his study of soln. of uranyl chloride. F. Mylius and R. Dietz suggested that both the trihydrated uranyl chloride and dihydrated uranyl hydroxychloride are addition products of uranic acid, H_4UO_5, with two and one mol. of hydrogen chloride respectively.

E. M. Péligot said that anhydrous uranyl chloride is yellow, deliquescent, and crystalline. F. Mylius and R. Dietz found the sp. gr. of the viscid aq. soln. to be 2·74, so that ordinary glass and quartz will float in the liquid. F. W. O. de Coninck found between 13·1° and 16·3°, for soln. with :

UO_2Cl_2 .	1	2	4	6	8	10 per cent.
Sp. gr. .	1·0056	1·0112	1·0215	1·0313	1·0418	1·0517

E. M. Péligot found that the salt is readily fusible, but apparently not very volatile. F. W. O. de Coninck said that the salt melts at the beginning of a red-heat. The absorption spectrum was measured by H. C. Jones and W. W. Strong, H. L. Howes, etc.—*vide supra*, physical properties of uranium. H. M. Vernon estimated the ionization from the colours. According to C. Dittrich, the mol. wt. calculated from the lowering of the f.p., $\theta°$ of dil. soln. when the theoretical value for UO_2Cl_2 is 341·1, the ionization factor, i, and the degree of ionization, a, for soln. with M mols per litre, are :

M . .	1	2	4	8	16
$\theta°$ . .	2·926°	1·338°	0·651°	0·331°	0·170°
Mol. wt. .	130·5	129·4	127·1	122·2	117·6
i . .	2·60	2·62	2·69	2·80	2·90
a . .	0·81	0·83	0·85	0·90	0·95

I. Lifschitz and S. B. Hooghoudt studied the Becquerel effect. The aq. soln. is acidic to litmus and congo-red, and the observations of F. Mylius and R. Dietz show that the soln. is hydrolyzed—*vide supra*. W. Hampe found that the molten anhydrous salt conducts the electric current, with the separation of black uranium dioxide. W. Hittorf also observed that the aq. soln. is decomposed by electrolysis into uranium dioxide and chlorine. C. Dittrich gave for the electrical conductivity, λ, of soln. with half a mol in v litres of water at 25° :

v .	4	8	16	32	64	128	256	512	1024
λ .	89·8	89·3	96·6	104·3	111·3	118·5	127·4	136·4	147·0

where $\lambda_{1024}-\lambda_{32}=42\cdot7$, corresponding with a two-stage ionization process. The results of L. G. Winston and H. C. Jones at 0° to 35°, and of A. P. West and H. C. Jones at 35°, 50°, and 65°, are :

v .		4	8	32	128	512	1024	2048	4096
	0 .	101·45	110·48	133·05	148·39	155·98	161·02	168·42	174·98

The maxima on the polarization curves of uranyl salt soln. were discussed by M. Shikata, E. B. Sanigar, W. Podrouzek, and P. Herasymenko ; and the electro-reduction of soln. of these salts by the mercury dropping cathode, by P. Herasymenko.

F. W. O. de Coninck observed that when thoroughly dried, anhydrous uranyl chloride is stable in a dry atmosphere ; and that an aq. soln., if air be excluded, slowly deposits, in light, a small quantity of uranic hydroxide, $UO_3.2H_2O$, which after some time partially redissolves. The decomposition is faster in the presence of air ; and when the aq. soln. is boiled. F. Mylius and R. Dietz found that the trihydrate is deliquescent, and that it can be heated to 100° without change, but at a higher temp. water, hydrogen chloride, and chlorine are given off, and the brownish-black substance which remains, after the salt has been heated over 400°, contains uranium trioxide. F. W. O. de Coninck found that when heated in *hydrogen*, the salt is reduced to the dioxide ; and when heated in *air*, chlorine is given off and uranosic oxide is formed. The anhydrous salt is freely soluble in *water*. At 18°, F. Mylius and R. Dietz found that 100 parts of water dissolve 746 parts of the trihydrate, and that the solubility increases with a rise of temp. The sat. soln. is yellowish-green. According to F. W. O. de Coninck, anhydrous uranyl chloride is slowly dissolved by conc. *hydrochloric acid* ; in the cold, *hydrogen sulphide* converts it into uranium dioxide, sulphur, and hydrogen chloride, and when heated, uranyl sulphate is formed ; *sulphuric acid* drives out hydrogen chloride to form uranyl sulphate ; and cold *selenic acid*, of sp. gr. 1·4, dissolves uranyl chloride, and when heated, chlorine is given off and uranyl selenite is formed. J. Persoz observed that uranyl salt soln. are reduced by *trithionic acid*. E. P. Lewis found that

uranium salts become phosphorescent when exposed to activated nitrogen. A. Rosenheim and F. Jacobsohn found that liquid *ammonia* forms a grey mass when it acts on anhydrous uranyl chloride ; F. F. Regelsberger did not obtain an *ammine* by the action of ammonia gas on an alcoholic soln. of the anhydrous chloride ; an unstable **uranyl tetramminochloride,** $UO_2Cl_2.4NH_3$, is formed by the action of ammonia on solid uranyl chloride, and if ammonia acts on the complex with ether, **uranyl diamminochloride,** $UO_2Cl_2.2NH_3$, is formed. W. Peters found that the dehydrated salt absorbs ammonia to form **uranyl hexamminodichloride,** $UO_2Cl_2.6NH_3$, and this compound, in vacuo, forms the diammine. According to J. M. Ordway, aq. ammonia added to a soln. of uranyl chloride gives a precipitate which again dissolves until half the hydrochloric acid is neutralized. F. W. O. de Coninck observed that cold *nitric acid* forms a yellow liquid, and when heated, chlorine and nitrous fumes are evolved and uranyl nitrate is formed ; an excess of nitric acid forms the acid salt. R. Böttger said that *phosphorus* does not reduce uranyl salt soln. J. Lifschitz obtained a complex with *hydroxymethylene camphor*. F. Mylius and R. Dietz found that the trihydrate is soluble in *alcohol*, and in *ether*. F. F. Regelsberger, E. Rimbach, C. G. Williams, A. R. Leeds, and H. Grossmann and B. Schück observed that uranyl chloride forms crystalline compounds with organic bases, ether, etc. The action of light on soln. of uranyl salts in the presence of alcohol, etc., was discussed in connection with the physical properties of uranium. J. Aloy and A. Valdiguié found that uranyl salts act catalytically by the simultaneous oxidation and reduction of dextrose and methylene-blue when soln. are exposed to sunlight in the absence of oxygen ; G. Berger examined the photochemical decomposition of formic acid. P. Walden, and H. Grossmann studied the effect of uranyl salt soln. on the rotatory power of soln. of sugar, and other optically active hydroxyl compounds. H. J. H. Fenton observed that uranyl salts give a red or brown coloration with dihydroxymaleic acid. S. Hakomori observed that sexivalent uranium salts form complexes with tartaric acid. E. F. Rousseau said that salts of uranium exposed to solar or ultra-violet radiation store the ultra-violet energy and produce photocatalytic effects in the sterilization or activation of ferments. A. Pil found that uranyl salt soln. do not coagulate a gelatin sol unless a trace of an alkali halide be also present. R. Rascanu prepared complex salts with pyridine, quinoline, 2-methylquinoline, antipyrine, pyramidon, and phenacetin.

E. M. Péligot observed that when uranyl chloride is heated with *potassium*, potassium chloride and uranium dioxide are formed ; K. Seubert and A. Schmidt found that when heated with *magnesium* some uranium is formed ; and F. W. O. de Coninck found that when heated with *zinc* dust or *iron* filings, it is reduced to uranium dioxide, but not by *copper* turnings. N. W. Fischer found that copper forms cuprous chloride and reduces a hydrochloric acid soln. of a uranyl salt to the uranous stage, and R. Arndt and W. Knop said that the action is facilitated by heat in the presence of a little platinic salt. V. Kohlschütter and H. Rossi found that uranyl salts are reduced by copper. J. L. C. Zimmermann observed that in sulphuric acid soln. uranyl salts are reduced by zinc only to the quadrivalent or uranous stage. N. W. Fischer found that hydrochloric acid soln. of uranyl salts are reduced to the uranous stage by zinc, *cadmium, tin, lead*, iron, or *cobalt*. The reaction with zinc was studied by I. Wertheim. The reduction of uranyl salt soln. to uranous salts by magnesium was observed by T. L. Phipson, A. Commaille, S. Kern, and G. A. Maack ; and by *aluminium*, by G. A. Maack. Molten *alkali hydroxide* forms alkali diuranate and a small proportion of normal uranate. When uranyl chloride is heated with *calcium hydroxide*, uranosic oxide and some calcium uranate are formed ; if air is excluded, dark grey uranium dioxide is produced and at a higher temp. dark reddish-brown uranium dioxide is formed. An excess of *calcium oxide* in air forms yellow calcium uranate, green or yellowish-green calcium diuranate, and very little uranosic oxide. When anhydrous uranyl chloride is heated with *barium hydroxide*, barium uranate and very little uranosic oxide are formed ; with *barium oxide*, at

a high temp., the main product is orange-yellow barium diuranate—*strontium oxide* acts in a similar manner. E. M. Péligot observed that complex salts are formed with the *alkali chlorides*.

According to F. W. O. de Coninck, the aq. soln. gives no precipitate with *hydrochloric acid*, hot or cold; *alkali-lye* gives an orange precipitate; aq. *ammonia*, a pale yellow precipitate, insoluble in excess; *methylamine*, a dark yellow precipitate, insoluble in excess; *sodium hydrocarbonate*, no precipitate; *alkali carbonate*, a pale yellow gelatinous precipitate, insoluble in excess; *sodium hydrophosphate*, a yellow gelatinous precipitate, insoluble in excess; *ammonium hydrosulphide*, a pale brown precipitate which in a few hours becomes reddish-brown; *hydrogen sulphide*, a small brown precipitate; *cobalt nitrate*, and *copper sulphate* give no change in 24 hrs.; *potassium cyanide*, a pale yellow precipitate, insoluble in excess; and with *potassium ferrocyanide and ferricyanide*, dark reddish-brown precipitates, insoluble in excess. For other reactions, *vide supra*, some reactions of analytical interest.

Uranyl chloride forms a series of complex salts of the general formula $2RCl.UO_2Cl_2$, or $R_2(UO_2)Cl_4$. E. Rimbach found that crystals of **ammonium uranyl tetrachloride**, $(NH_4)_2(UO_2)Cl_4.2H_2O$, are obtained from a soln. of a mol of uranyl chloride and 2 mols of ammonium chloride in conc. hydrochloric acid, after concentration to a syrupy liquid. E. M. Péligot previously obtained this salt from a soln. of uranium trioxide and ammonium chloride in hydrochloric acid, or from a soln. of ammonium uranate in that acid. The rhombohedral crystals are very deliquescent and freely soluble in water. The solubility data shown in Table I indicate that the salt is decomposed by water, the soln. is richer in uranyl chloride, and the solid is a mixture of ammonium chloride and undecomposed ammonium uranyl tetrachloride. The corresponding **tetramethylammonium uranyl tetrachloride**, $2N(CH_3)_4Cl.UO_2Cl_2$, and **tetraethylammonium uranyl chloride**, $2N(C_2H_5)_4Cl.UO_2Cl_2$, as indicated in Table I, are not decomposed in aq.

TABLE I.—THE SOLUBILITY OF THE ALKALI AND AMMONIUM URANYL
TETRACHLORIDES.

Complex salt	Temp.	100 parts of solution contain				Atomic or mol. ratios in solution
		UO_2	R	Cl	Total	$UO_2 : R : Cl$
$2NH_4Cl.UO_2Cl_2$	15°	40·67	3·51	19·15	—	1 : 1·59 : 3·59

	80·3°	30·69	19·13	15·86	65·79	1 : 1·98 : 3·95
$2CsCl.UO_2Cl_2$	29·75°	22·12	22·37		56·24	1 : 2·06 : —

soln. **Methylammonium uranyl tetrachloride**, $2NH_3(CH_3)Cl.UO_2Cl_2$; **dimethylammonium uranyl tetrachloride**, $2NH_2(CH_3)_2Cl.UO_2Cl_2$; and **trimethylammonium uranyl tetrachloride**, $2NH(CH_3)_3.UO_2Cl_2$, were also prepared. H. Grossmann and B. Schück prepared **ethylenediamine uranyl chloride**, $C_2H_6(NH_2)_2(UO_2)Cl_4.2H_2O$, in yellow, hygroscopic, prismatic crystals, melting at 219°. Attempts by E. Rim-

bach to prepare **hydroxylamine uranyl tetrachloride,** $2NH_4OCl.UO_2Cl_4$, in aq. soln. were not successful; and in the attempts to make **hydrazine uranyl tetrachloride,** reduction always occurred. J. Aloy prepared **sodium uranyl tetrachloride,** $Na_2(UO_2)Cl_4$, by passing the vapour of uranyl chloride over heated sodium chloride, and similarly with **potassium uranyl tetrachloride,** $K_2(UO_2)Cl_4$. The golden-yellow crystals melt at a red-heat without vaporizing; the salt is freely soluble in water, and in dil. alcohol. E. M. Péligot prepared the *dihydrate,* $K_2(UO_2)Cl_4.2H_2O$, from a soln. of the components, using an excess of potassium chloride; J. J. Berzelius recommended using soln. with at least 15 per cent. of hydrochloric acid. E. Rimbach, and H. Bürger used an excess of uranyl chloride. J. A. Arfvedson added that if potassium chloride is not present in excess, the double salt crystallizes from the soln. with difficulty; but since both salts crystallize from the soln. at the same time, the crystals of the double salt must be picked out from those of potassium chloride. E. M. Péligot prepared the salt from a soln. of potassium uranate in a large excess of hydrochloric acid. The yellowish-green, four or six-sided plates were shown by C. F. Rammelsberg, and F. de la Provostaye to be triclinic pinacoids with the axial ratios $a:b:c = 0.607:1:0.560$, and $a = 80°\ 41'$, $\beta = 77°\ 42'$, and $\gamma = 91°\ 18'$. J. A. Arfvedson found that the hydrated salt loses its water at a temp. a little above $100°$, and the anhydrous compound melts at the beginning of a red-heat. When heated above this temp. it is partially decomposed, with the evolution of chlorine; and at a still higher temp. E. M. Péligot observed that fused potassium chloride is formed, with scaly crystals of uranium dioxide in suspension. H. Becquerel studied the absorption spectrum. J. A. Arfvedson found that when heated in hydrogen the salt is decomposed. E. M. Péligot observed that the salt is freely soluble in water; and E. Rimbach, and H. Bürger found the solubility data indicated in Table I. The results show that at low temp. the complex salt is resolved by water into its components, so that a greater propor-tion of uranyl chloride passes into soln. The ground-mass is then a mixture of potassium chloride and potassium uranyl chloride, in agreement with E. M. Péligot's observation that on evaporating the aq. soln., potassium chloride crystallizes out, while uranyl chloride remains in soln. E. Rimbach observed that at about $60°$ the soln. and solid have the same composition, showing that *das Salz ist von da an untersetzt in Wasser löslich*—or, possibly, that the solubilities of the components are the same. J. Aloy said that the heat of soln. of a mol of the salt in 1000 to 2500 mols of water at $18°$ to $20°$ is 2 Cals. J. J. Berzelius found that the salt is reduced with vivid incandescence when it is heated with potassium; uranium dioxide and potassium chloride are formed. J. O. Perrine observed no ultra-violet fluorescence in the X-rays. E. Rimbach, and H. Bürger prepared **rubidium uranyl tetrachloride,** $Rb_2(UO_2)Cl_4.2H_2O$, in yellowish-green crystals, as in the analogous case of the potassium salt. The solubility data, Table I, show that the salt is not decomposed by water, from which solvent it can be crystallized unchanged. H. L. Wells and B. B. Boltwood prepared **cæsium uranyl tetrachloride,** $Cs_2(UO_2)Cl_4$, in rhombic plates, by passing hydrogen chloride into a well-cooled, conc. soln. of 10 to 50 grms. of cæsium chloride and 10 to 50 grms. of uranyl chloride; and by evaporating a soln. of 15 to 50 grms. of cæsium chloride and 15 to 50 grms. of uranyl chloride. E. Rimbach, and H. Bürger obtained it by evaporating a soln. of 2 mols of cæsium chloride and one mol of uranyl chloride. The solubility data are shown in Table I; like the rubidium salt, the cæsium salt is not decomposed in aq. soln. H. L. Wells and B. B. Boltwood said that the salt is decomposed when calcined, forming uranosic oxide. J. O. Perrine observed no ultra-violet fluorescence in the X-rays.

§ 18. The Uranium Bromides and Iodides

G. Alibegoff,[1] and J. L. C. Zimmermann obtained **uranium tribromide,** UBr_3, by the action of hydrogen on uranium tetrabromide heated to near its m.p. The reduction could not be carried further than the tribromide. The dark brown, needle-like crystals of the tribromide prepared by G. Alibegoff are very hygroscopic. The vap. density could not be determined. When molten the salt is dark green. It dissolves in water with a hissing noise and the development of much heat. The soln. furnishes a characteristic absorption spectrum. When the violet soln. is allowed to stand exposed to air, or when it is shaken in air, it becomes dirty brown, then dirty green, and finally emerald-green characteristic of uranous salt soln., depositing a reddish powder. H. Löbel reduced electrolytically a dil. soln. of uranic acid in hydrobromic acid, when the yellow soln. becomes green, and finally red. The addition of sulphuric acid produces a brown, crystalline precipitate, which, becoming green, gives off hydrogen. A cold, sat. soln. of potassium sulphate gives a precipitate similar to that obtained with a soln. of the trichloride.

J. L. C. Zimmermann prepared **uranium tetrabromide** or **uranous bromide**, UBr_4, by passing bromine vapour along with a current of carbon dioxide or nitrogen over a heated mixture of carbon and uranium dioxide or uranosic oxide. A similar process was employed by H. Hermann, and A. Colani. A. von Unruh said that the product is a mixture of uranyl and uranous bromides. T. W. Richards and B. S. Merigold also prepared the salt in this manner, and added that it can be purified by sublimation in a dry atm. of bromine or nitrogen and rigorously excluding all traces of air or oxygen. A. Colani obtained the tetrabromide at a temp. above its m.p. but below its temp. of vaporization. According to C. F. Rammelsberg, the dark green soln. of hydrated uranous oxide in hydrobromic acid, when evaporated over sulphuric acid, deposits dark green crystals, and dries to a highly deliquescent mass. Analyses agree with the *octohydrate*, $UBr_4.8H_2O$, but this has not been confirmed. When the aq. soln. is heated, it gives off hydrogen bromide and deposits a black powder which he thought to be uranous oxide. J. L. C. Zimmermann said that the anhydrous salt, during its preparation, collects as a sublimate of dark brown or black plates—H. Hermann said fine needles. J. L. C. Zimmermann found that when the salt is heated in an inert gas, it melts and gives off a brown vapour which condenses as a sublimate of the original salt. T. W. Richards and B. S. Merigold found the sp. gr. to be 4·838 at 21°. J. L. C. Zimmermann observed that the vap. density 19·46 agrees with the theoretical value 19·36 required for UBr_4. H. Hermann reported that in contact with air the anhydrous salt fumes, and rapidly deliquesces to a dark emerald-green liquid ; it dissolves in water with a hissing noise, forming a green soln. which exhibits the characteristic reactions of the uranous salts. The green, aq. soln. of the tetrabromide is even less stable than that of the tetrachloride ; it readily gives off hydrogen bromide, and oxidizes to the yellow uranyl bromide. A. von Unruh said that the tetrabromide is insoluble in alcohol, and R. Sendtner, insoluble in ether. J. L. C. Zimmermann heated the tetrabromide with bromine in a sealed tube at 230° for a long time, but observed no change, and no sign of the formation of the **uranium pentabromide**, UBr_5.

J. Aloy passed the vapour of the tetrabromide, in a current of carbon dioxide, over red-hot sodium bromide, and obtained a dark green mass of **sodium uranous hexabromide**, Na_2UBr_6, and similarly with **potassium uranous hexabromide**, K_2UBr_6. These salts are fusible, freely soluble in water, and the aq. soln. on evaporation does not yield the double salt. They resemble the corresponding hexachlorides, but the colour is a darker green.

According to H. Hermann, the anhydrous **uranyl bromide**, UO_2Br_2, is obtained simultaneously with uranium tetrabromide when the latter is obtained by passing bromine vapour over a mixture of carbon and uranosic oxide. Uranyl bromide is rather more volatile than uranium tetrabromide. R. Sendtner extracted with ether the mixture of uranyl and uranous bromides obtained by heating uranium dioxide in a current of bromine vapour. The ethereal soln. when evaporated in vacuo furnishes fluorescent, yellowish-green needles of uranyl bromide. A. von Unruh prepared the anhydrous salt by treating the heptahydrate with amyl alcohol, decanting off the water, and boiling the soln. J. B. Berthemot boiled uranium dioxide with bromine-water, or dissolved uranium trioxide in hydrobromic acid, and obtained, on evaporation, a yellow liquid which deposited yellow needles of the *heptahydrate*, $UO_2Br_2.7H_2O$. R. Sendtner obtained the salt in a similar manner ; and C. F. Rammelsberg said that the green mixture of uranium tetrachloride and potassium bromate soon becomes yellow owing to the liberation of bromine and the formation of this salt. A. von Unruh prepared the tetrahydrate repeatedly by evaporating a soln. of uranyl acetate and hydrobromic acid on a water-bath, then with water, and finally evaporating the aq. soln. in vacuo over sulphuric acid. The flat, yellow needles of the heptahydrate, said J. B. Berthemot, have a strong, styptic taste ; and when they are dried at a high temp., they assume an orange colour, and give off hydrogen bromide, while at a red-heat they evolve bromine and form uranosic oxide. H. C. Jones and W. W. Strong measured the

absorption spectra of a soln. of the salt. The crystals are very deliquescent, and, according to F. W. O. de Coninck, give off hydrogen bromide to form hydrated uranium dioxide. R. Sendtner said that the salt is freely soluble in water and in alcohol; and, added A. von Unruh, in ether. The aq. soln. hydrolyzes and deposits hydrated uranium trioxide. F. W. O. de Coninck observed that the reactions of the aq. soln. are characteristic of those of the uranyl salts—*vide supra*, uranyl chloride. If dry ammonia be passed into a dry ethereal soln. of uranyl bromide, a complex salt, $UO_2Br_2(NH_3)_2.(C_2H_5)_2O$, is deposited, and if this salt be exposed to a current of dry air, almost all the ether is driven off and egg-yellow **uranyl diamminobromide,** $UO_2Br_2.2NH_3$, is formed; and the same compound is formed when dry ammonia is passed into a dry amyl alcohol soln. of uranyl bromide, the precipitate washed with dry ether and alcohol, and dried in a current of warm air. If the product be allowed to stand in an atm. of dry ammonia for a long time, it passes into **uranyl triamminobromide,** $UO_2Br_2.3NH_3$. By treating the diammine or the anhydrous salt with liquid ammonia, deep orange-red, amorphous **uranyl tetramminobromide,** $UO_2Br_2.4NH_3$, is formed, but it is stable only below 5°. R. Rascanu prepared complex salts with antipyrine, and phenacetin.

According to R. Sendtner, if a soln. of ammonium diuranate be dissolved in an excess of hydrobromic acid, and the soln. concentrated by evaporation, it furnishes yellowish-brown, rhombic plates of **ammonium uranyl tetrabromide,** $(NH_4)_2(UO_2)Br_4.2H_2O$, which are so deliquescent that they are difficult to dry. The salt is freely soluble in water. The salt cannot be recrystallized from water. The corresponding **potassium uranyl tetrabromide,** $K_2(UO_2)Br_4.2H_2O$, was prepared in a similar way.

H. Löbel could not prepare a soln. of **uranium triiodide,** UI_3, by the electrolytic process which he employed for the trichloride and tribromide. According to C. F. Rammelsberg, hydrated uranium dioxide forms a dark green soln. of **uranium tetraiodide,** UI_4, when dissolved in hydriodic acid. If the soln. be evaporated spontaneously, it turns brown, and gives off free iodine, leaving a black, crystalline mass which contains some tetraiodide and forms a reddish-brown soln. with water. R. Sendtner found that if the soln. be extracted with ether, and the yellow, ethereal liquid be evaporated, it is decomposed. Neither H. Hermann nor R. Sendtner could obtain an iodide by the action of iodine vapour on a red-hot mixture of carbon and uranium dioxide; nor did R. Sendtner succeed in producing an iodide by passing hydrogen iodide over the heated dioxide. A. Colani could not obtain the pure tetraiodide by the action of hydrogen iodide on uranium tetrachloride, but M. Guichard found that by heating a mixture of iodine and uranium in a sealed tube at 500°, anhydrous uranium tetraiodide collects as a crystalline sublimate. The black, needle-like crystals have a sp. gr. 5·6 at 15°; the m.p. is about 500°; and volatilization occurs between 500° and 600° in vacuo. The tetraiodide is reduced when heated in hydrogen; when kept in dry air, it acquires a superficial crust of iodine crystals, and oxygen is absorbed; it inflames at a low temp. in dry oxygen or dry air, forming green uranosic oxide; in moist air it rapidly deliquesces to a brown liquid containing free iodine, and in a few hours, in the presence of an excess of water, forms a yellow liquid, which when heated precipitates green hydrated uranium trioxide. The salt dissolves in water to form a green, acidic soln. which gives the characteristic reactions of uranous salts. When the tetraiodide is treated in the cold with chlorine, it is decomposed, yielding uranium tetrachloride and iodine trichloride.

A. von Unruh observed that **uranyl iodide,** UO_2I_2, cannot be prepared like the corresponding chloride and bromide, since neither iodine vapour nor hydrogen iodide reacts with a red-hot mixture of uranium dioxide and carbon; nor did J. Aloy obtain definite results by the action of iodine vapour on uranium dioxide at various temp. A. von Unruh obtained a soln. of uranyl iodide by the action of hydriodic acid on uranyl acetate, which decomposes into uranium dioxide, iodide, and hydrogen iodide when it is warmed on a water-bath to drive off the acetic acid.

If, however, the soln. be evaporated in vacuo over sulphuric acid, it suffers only partial decomposition, and after some days deposits crystals of the salt. J. Aloy prepared the salt by adding a slight excess of a soln. of barium iodide in dry ether to an ethereal soln. of uranyl nitrate, and evaporating the red soln. in vacuo. The red, crystalline mass deliquesces in air, and it decomposes with the separation of iodine. The yellow, aq. soln. does not yield uranyl iodide on evaporation, since it decomposes into hydriodic acid, iodine, etc. The salt is freely soluble in alcohol, ether, and benzene. A. von Unruh obtained a soln. of the salt by adding an excess of uranium trioxide to freshly-prepared hydriodic acid, agitating the filtered soln. with amyl alcohol, removing the aq. layer in a separatory funnel, and boiling the amyl alcohol soln. to eliminate water. The yellow liquid soon becomes brown. G. Truttwin prepared a soln. of uranyl iodide by double decomposition in alcoholic soln. A. von Unruh prepared yellow **uranyl diamminoiodide,** $(UO_2)I_2.2NH_3$, by passing dry ammonia into a dry, ethereal soln. of uranyl iodide, and removing ether from the precipitated $UO_2I_2.2NH_3.(C_2H_5)_2O$, in vacuo, or in a current of dry air ; and also by passing dry ammonia into the dry amyl alcohol soln. of uranyl iodide, washing the precipitate with ether, and removing the ether in a current of dry air. If the product be kept in an atm. of dry ammonia, it forms orange-red **uranyl triamminoiodide,** $UO_2I_2.3NH_3$; and if treated with liquid ammonia, it forms **uranyl tetramminoiodide,** $UO_2I_2.4NH_3$, which is very unstable, for it quickly decomposes at a temp. above 5°. G. Truttwin prepared **bismuth uranyl iodide,** $UO_2I_2.BiI_3$.

§ 19. Uranium Sulphides and Oxysulphides

J. L. C. Zimmermann [1] said that uranium has not a great affinity for sulphur. G. Alibegoff obtained what he regarded as **uranium monosulphide,** US, by heating to redness uranium hemitrisulphide in a current of hydrogen for 30 to 70 hrs. The black, amorphous powder glows when heated in air, and it behaves towards acids like **uranium hemitrisulphide,** or **uranium sesquisulphide,** U_2S_3, which he prepared by heating uranium tribromide in a current of hydrogen sulphide. The greyish-black, needle-like crystals are pseudomorphs after the tribromide. When the hemitrisulphide is exposed to air, it gives off hydrogen sulphide ; when heated in air, it glows and forms uranosic oxide ; dil. and conc. hydrochloric and nitric acids are without action ; fuming nitric acid oxidizes it with incandescence ; aqua regia oxidizes it quietly ; and bromine and hydrochloric acid attack it a little. E. Beutel and A. Kutzelnigg observed no anodic deposition of sulphide from thiosulphate soln.

According to E. M. Péligot, uranium unites with incandescence with sulphur at its b.p., forming **uranium disulphide,** or **uranous sulphide,** US_2. H. Hermann found that at a red-heat, hydrogen sulphide decomposes uranium tetrachloride

quietly and without incandescence, forming uranium disulphide and hydrogen chloride. A. Colani obtained it by heating sodium uranous hexachloride in hydrogen sulphide: the sodium salt is better than uranium tetrachloride because it is less volatile; the reaction begins at 500°, and progresses better at a higher temp. A high temp. is necessary for the production of good crystals. When the apparatus has cooled, the product is quickly washed with cold, air-free water, when the disulphide remains. A. Colani also prepared the disulphide by double decomposition of a sulphide of magnesium, aluminium, antimony, or tin with sodium uranous hexachloride in an atm. of hydrogen. Stannous sulphide gave the best results. The product contains a little hemitrisulphide; and if air be not rigorously excluded, some dioxysulphide may be formed. C. F. Rammelsberg dropped an aq. soln. of uranium tetrachloride in an excess of ammonium sulphide and obtained a black precipitate, which when washed and dried proved to be a mixture of uranium hydroxide and sulphur. A. Colani described uranium disulphide as a black or iron-grey, crystalline powder. H. Hermann obtained black, four-sided columns by heating the powder with borax at a white-heat. According to P. Groth, the tetragonal plates have the axial ratio $a : c = 1 : 0.6152$. The streak on porcelain is grey. A. Colani said that the disulphide does not decompose or melt between 1000° and 1100°; but M. Picon found that the disulphide is decomposed or dissociated at 1200° to 1300°. H. Hermann found that it is slowly oxidized by moist *air*, forming hydrogen sulphide and a yellow basic uranyl sulphide; when heated in air, sulphur dioxide is evolved and uranosic oxide is formed. A. Colani added that if the powder is projected into a flame, it burns in sparks. Cold *water* reacts very slowly; water vapour acts energetically at a red-heat, forming uranium dioxide, hydrogen sulphide, and sulphur. H. Hermann found that the disulphide is vigorously decomposed by *chlorine* without incandescence; dil., cold or boiling *hydrochloric acid* is almost without action; the cold, conc. acid dissolves the disulphide, forming the tetrachloride without the separation of sulphur. A. Colani added that the action is slow with the dil. acid, faster with the conc. acid, especially when warmed. H. Hermann said that *nitric acid* oxidizes it to uranyl sulphate, and A. Colani added that uranyl nitrate, sulphuric acid, and sulphur are formed. A. Verneuil found that the addition of one-thousandth part of uranium disulphide alters the character of the phosphorescence of calcium sulphide.

H. Rose [2] prepared **uranium dioxytetrasulphide**, $U_3O_2S_4$, or $UO_2.2US_2$, but its composition was established by H. Hermann. The former prepared it by heating uranosic oxide and the latter by heating uranium dioxide or ammonium uranate in the vapour of carbon disulphide alone, or carried along by a current of carbon dioxide —the same product is obtained if the uranium dioxide be at a red-heat or at a white-heat, but at the higher temp. some free carbon and sulphur are formed. J. A. Arfvedson observed that this compound is formed along with a little uranium disulphide when hydrogen sulphide is passed over heated uranosic oxide; L. R. Lecanu, and J. J. Ebelmen, when uranosic oxide or uranium dioxide is heated with sulphur, or, according to H. Hermann, sulphur and ammonium chloride; and H. Hermann, by heating uranyl sulphate in hydrogen sulphide or with potassium pentasulphide, or by heating sodium uranate mixed with sulphur and ammonium chloride. According to H. Rose, and H. Hermann, the greyish-black or yellowish-black powder smells of hydrogen sulphide when triturated in a mortar; and it burns when heated in air to form uranosic oxide. Uranium dioxytetrasulphide is slowly oxidized by chlorine-water; and a mixture of potassium chlorate and hydrochloric acid inflames the powder. J. J. Berzelius observed that it is only slightly attacked by dil. hydrochloric acid; but H. Hermann added that it is soluble in conc. hydrochloric acid, forming uranous chloride without the separation of sulphur. J. J. Berzelius observed that cold nitric acid dissolves the dioxytetrasulphide with the separation of sulphur, whilst H. Hermann added that the fuming acid decomposes it with incandescence.

J. Milbauer obtained **uranyl sulphide**, UO_2S, in black, tetragonal, acicular
crystals, by fusing together 12 parts of dry potassium thiocyanate, 3 parts of uranosic oxide, and 5 parts of sulphur. W. W. Coblentz found that uranyl sulphide exhibits no photoelectric sensitivity. An impure form was prepared by H. Hermann by adding ammonium sulphide to an aq. or alcoholic soln. of a uranyl salt. The complete precipitation of the uranyl sulphide occurs only after the warm mixture has stood for some time with a very small excess of ammonium sulphide. The olive-green precipitate is then crystalline and easily filtered. When the brown precipitate is washed with air-free water, it is hydrolyzed to uranium dioxide; and, added A. Remelé, if washed in air, it forms yellow uranyl hydroxide. A. Remelé found that the precipitate from the alcoholic soln. can be washed with alcohol without decomposition, and after drying in vacuo over potassium hydroxide, one preparation contained 18 per cent. H_2O, 1·7 per cent. ammonium sulphide, and 80·3 per cent. UO_2S. Uranyl sulphide oxidizes in air at 180° to 240°, forming uranosic oxide. It forms with water a brown soln., which is decolorized by exposure to air, and uranyl hydroxide is precipitated. A brown liquid is also formed when uranyl sulphide is treated with aq. alcohol, but not with absolute alcohol, and when the brown soln. is boiled for some hours it becomes green, though the brown coloration returns as the soln. cools. Uranyl sulphide forms a green soln. of uranous chloride when treated with conc. hydrochloric acid, in the absence of air, and sulphur is deposited; dil. acids also dissolve it, with the separation of two-thirds to three-fourths of the sulphur and the evolution of a little hydrogen sulphide. It is also soluble in acetic acid and in a soln. of ammonium carbonate. P. Berthier found that precipitated uranyl sulphide dissolves in sulphurous acid, and when the yellow soln. is boiled, hydrated oxide is precipitated; and A. Remelé found that sulphur dioxide converts the precipitate into uranium dioxide. G. Buchner observed that uranyl sulphide dissolves in a soln. of sodium pyrophosphate. According to A. Remelé, alkali hydroxides decompose uranyl sulphide, forming alkali uranate; whilst sodium, potassium, and barium sulphides appear to form very unstable complex salts. A. Remelé obtained a green precipitate of impure **barium uranyl sulphide,** $6BaS.UO_2S.nH_2O$, by adding barium nitrate to a soln. of uranyl sulphide in ammonium sulphide, rapidly washing with cold water and drying in vacuo. A brown salt was obtained by adding an excess of an aq. soln. of barium sulphide to an alcoholic soln. of uranyl nitrate, washing with alcohol, and drying in vacuo.

J. J. Berzelius observed that precipitated uranyl sulphide dissolves in an excess of a soln. of ammonium sulphide to form a dark brown liquid. A. Remelé found that if freshly-precipitated uranyl sulphide is warmed with an excess of ammonium sulphide at about 40° or 50°, it is transformed into a mixture of uranium dioxide and sulphur; it is, however, more stable in the presence of a small proportion of a metal sulphide. Uranyl sulphide precipitated from alcoholic soln. is not decomposed by boiling it with an excess of a soln. of ammonium sulphide, nor is it reddened when allowed to stand in contact with a cold soln. of ammonium sulphide, whereas A. Patera showed that uranyl sulphide precipitated by ammonium sulphide from aq. soln. of a uranyl salt becomes dark red when allowed to stand in the cold in contact with an excess of ammonium sulphide for 12 to 24 hrs. The red product was called **uranium-red** by A. Remelé. L. E. Rivot said that the change proceeds more quickly if the ammonium sulphide employed contains a little uranyl sulphide in soln.; and A. Remelé observed that a soln. of sulphides of potassium, sodium, or barium sulphide does not produce the red colour. J. L. C. Zimmermann found that a cold soln. of potassium hydrosulphide does not transform uranyl sulphide into the red compound; whilst ammonium hydrosulphide and calcium hydrosulphide do not form the red compound in cold or hot soln.; rather do they decompose the uranyl sulphide into uranium dioxide and sulphur; on the other hand, a warm soln. of barium hydrosulphide does produce uranium-red. J. J. Berzelius observed that if hydrogen sulphide be passed for a long time into water with an alkali uranate in suspension, the precipitate is orange-red; and H. Hermann, that if a soln. of a uranyl salt be treated with an excess of ammonia, followed by hydrogen sulphide,

a red colour is produced, but if a uranyl salt soln. be treated with hydrogen sulphide and then with ammonia, a brown colour is produced. A. Remelé observed that if a uranyl salt soln. be treated with ammonium sulphide and hydrogen sulphide be passed into the liquid, uranium-red is formed. According to J. L. C. Zimmermann, a black and a red substance are produced when precipitated uranyl sulphide is left for a long time in contact with a cold soln. of ammonium sulphide. If the ammonium sulphide contains thiosulphate—formed by the action of atm. oxygen on the sulphide—the red body is produced, but in the absence of thiosulphate, the black body alone is formed. The black substance is considered to be a complex uranium oxide, $U_3O_8.2UO_3$, whereas the red substance consists of an oxygen compound which, in addition to sulphur, contains a base—sodium, potassium, ammonium, or barium—as well as uranyl sulphide. J. L. C. Zimmermann also made uranium-red by treating a soln. of uranyl nitrate, acetate, or sulphate with freshly-prepared potassium hydrosulphide and keeping the liquid warm. V. Kohlschütter thus summarizes his observations on uranium-red :

(1) Alkaline, neutral, and even slightly acidic soln. of uranic acid are reduced by hydrogen sulphide. (2) In the presence of alkali-lye the reduction may be retarded if the action of hydrogen sulphide on the alkali uranate takes place in a soln. containing an excess of uranyl sulphate or nitrate. (3) Under these conditions an orange-yellow compound is produced, yielding the blood-red substance " uranium-red " when treated with alkali-lye. (4) Uranium-red contains uranium, sulphur, and alkali metal in the proportions 5 : 2 : 5. (5) All the uranium is present as trioxide. (6) One of the atoms of the alkali metal is more loosely combined than the others. When this is removed, the yellow intermediate compound is produced ; it is feebly acid, and contains uranium, sulphur, and alkali in the proportions 5 : 2 : 4. (7) Treatment with dil. hydrochloric acid eliminates one-half the sulphur from this compound in the form of hydrogen sulphide and the remainder as the free element ; this suggests that uranium-red contains a disulphide residue which acts as the carrier of the loosely attached atom of the alkali metal. (8) In the uranium-alkali residue, $5UO_3.2R_2O$, the four alkali atoms may be replaced by the alkaline earths without altering the chemical character of the compound ; the five mols. of uranic acid are therefore grouped in one complex, which takes part, as such, in reactions.

V. Kohlschütter's results are summarized in the following formulæ :

$$\begin{array}{cc} \mathrm{HO}\!\!\diagdown \\ \mathrm{HS.S}\!\!\diagup \end{array}\!\!\mathrm{U}\!\!\equiv\!\!(\mathrm{O.UO_2.OR})_4 \qquad\qquad \begin{array}{cc} \mathrm{HO}\!\!\diagdown \\ \mathrm{RS.S}\!\!\diagup \end{array}\!\!\equiv\!\!\mathrm{U(O.UO_2.OR)}_4$$

Parent Acid.   Uranium-red.

V. Kohlschütter obtained **potassium uranium hydroxyhydrodisulphotetrauranate,** $HS.S.U(OH)(O.UO_2.OK)_4$, or $2K_2O.5UO_3.H_2S_2$, by passing a current of carbon dioxide or hydrogen sulphide into water with freshly prepared uranium-red in suspension ; or by the protracted washing of the uranium-red with water. It is converted back into uranium-red by treatment with dil. potash-lye. *Potassium uranium-red*, or **potassium uranium hydroxydisulphotetrauranate,** $2K_2O.KHS_2.5UO_3.5H_2O$, or $KS.S.U(OH)(O.UO_2.OK)_4.5H_2O$, was obtained by the following process :

Agitate 140 c.c. of potash-lye (containing 11 grms. of potassium hydroxide per litre) with 100 c.c. of a soln. of uranyl nitrate (50 grms. per litre) ; pass a vigorous current of hydrogen sulphide through the product until the orange-red precipitate is formed ; pass a vigorous current of air, by suction ; agitate the moist cake with a soln. of potassium carbonate heated on a water-bath for half an hour ; wash the product by suction, with water made feebly alkaline ; dry it on a porous tile ; and finally wash the product successively with alcohol, carbon disulphide, and ether.

V. Kohlschütter also prepared *sodium uranium-red*, or **sodium uranium hydroxydisulphotetrauranate,** but he did not analyze it ; **ammonium uranium hydroxyhydrodisulphotetrauranate,** $2(NH_4)_2O.5UO_3.H_2S_2.NH_3.4H_2O$, or $HS.S.U(OH)(O.UO_2.ONH_4)_4.4H_2O$, was obtained as well as the corresponding *ammonium uranium-red*, or **ammonium uranium hydroxydisulphotetrauranate,** $(NH_4)S.S.U(OH)(O.UO_2.ONH_4)_4.nH_2O$. A. Patera found that the corresponding products with the alkalies and alkaline earths in place of ammonia can be obtained by boiling

the ammonium salt with salts of the alkalies or alkaline earths. R. Salvadori found that if hydrogen uranate is treated with hydrogen sulphide in the presence of an excess of uranyl nitrate or sulphate, an orange-yellow precipitate of **hydrazine uranium hydroxyhydrodisulphotetrauranate**, $2(N_2H_5)_2O.5UO_3.H_2S_2.6H_2O$, is formed. When the hydrogen sulphide is removed, and an excess of hydrazine hydrate is added, *hydrazine uranium-red*, or **hydrazine uranium hydroxydisulphotetrauranate**, $2(N_2H_5)_2O.5UO_3.HS_2(N_2H_5).4H_2O$, is formed. The substance decomposes a little above 100°. In the air it slowly loses one mol. of hydrazine. The compound remaining readily absorbs a mol. of ammonia, becoming blood-red. Hydrazine uranium-red is also obtained when " uranium-red " is treated with hydrazine. V. Kohlschütter prepared **barium uranium hydroxyhydrodisulphotetrauranate**, $2BaO.5UO_3.H_2S_2.10H_2O$, and found that it loses half its water at 165°. *Barium uranium-red*, or **barium uranium hydroxydisulphotetrauranate**, was obtained by V. Kohlschütter in an impure state; and similarly with *strontium uranium-red*, or **strontium uranium hydroxydisulphotetrauranate**, and with *calcium uranium-red*, or **calcium uranium hydroxydisulphotetrauranate**. According to V. Auger and J. N. Longinescu, the red uranium compounds are amorphous salts of a *sulphouranic acid*, $H_6U_5S_2O_{16}$, or $H_{10}U_{16}S_4O_{31}$, which plays the part of quinquevalent or quadrivalent anion respectively for the red potassium and ammonium salts, and for the orange and red barium salts.

§ 20. The Uranium Sulphates

A. Rosenheim and H. Loebel [1] prepared a sulphate of tervalent uranium the composition of which is probably **uranium hydrodisulphate**, or **hydrosulphatosulphate**, $UH(SO_4)_2$, or $U(HSO_4)(SO_4)$, or maybe $U(HSO_4)_3$. A soln. of uranium trichloride was obtained in a large excess of hydrochloric acid, by the electrolytic reduction of a soln. of uranium trioxide in hydrochloric acid of sp. gr. 1·12, with a mercury cathode, cooling the soln. to 0° towards the end of the reduction. When this soln. is mixed with fairly conc. sulphuric acid, both cooled to 0°, deep brown crystalline leaflets of this sulphate separate out. They are washed with anhydrous acetic acid. The salt can be kept under the mother-liquor for some hours out of contact with air ; on drying, it quickly forms uranous sulphate, $U(SO_4)_2$. Water oxidizes it to uranous sulphate, with the evolution of hydrogen. E. Müller and A. Flath, and

D. T. Ewing and E. F. Eldridge studied the electrometric titration of soln. of uranous sulphate with potassium permanganate or dichromate.

The existence of anhydrous **uranium disulphate,** or **uranous sulphate,** $U(SO_4)_2$, has not been established, although a product with this composition was obtained by F. Giolitti and G. Bucci [2] by heating the octohydrate at 300°. Hydrates with $\frac{1}{2}$, $1\frac{1}{2}$, 2, 3, 4, 5, 6, 7, 8, and $9H_2O$ have been reported either as stages in the drying of the higher hydrates or as definite products of crystallization from soln. of the salt. The individualities of the di-, tetra-, octo- and enneahydrates have alone been established, though the evidence is based on only a partial study of the equilibrium conditions—*vide infra*, Fig. 12. F. Giolitti and G. Liberi said that many of the phenomena presented by the uranous sulphates are almost certain indications that in these salts the sulphuric acid residue does not form ions by itself, but constitutes part of certain complex ions, which contain also uranium. This explains the large

FIG. 12.—Solubility Curves of the Tetra- and Octohydrates of Uranous Sulphate.

number of different salts obtained, the complexity of their formulæ, and the fact that uranous sulphates of identical composition often exhibit divergent crystalline forms and other physical and chemical properties. G. N. Wyrouboff came to a similar conclusion.
V. Kohlschütter obtained the *dihydrate*, $U(SO_4)_2.2H_2O$, in grey needles, by adding conc. sulphuric acid to the sulphuric acid soln. of the *tetrahydrate*, $U(SO_4)_2.4H_2O$. J. J. Ebelmen prepared the tetrahydrate by dissolving uranosic oxide in an excess of hot conc. sulphuric acid, and evaporating the soln. in vacuo. The mother-liquor contains uranyl sulphate. It is better, however, before evaporating the soln., to mix it with a little alcohol and expose it in a closed flask to sunlight. V. Kohlschütter obtained this salt by triturating uranous oxalate with conc. sulphuric acid, pouring the mush into alcohol, and washing the crystals successively with alcohol and ether. F. Giolitti and G. Bucci exposed to direct sunlight a mixture of a gram of uranyl sulphate, 12 grms. of water, 6 grms. of alcohol, and 3·12 to 4·68 grms. of sulphuric acid, or a gram of uranyl sulphate, 6 grms. of 95 per cent. alcohol and 0·9 grm. of sulphuric acid. J. Aloy and G. Auber added in small portions at a time powdered or a conc. soln. of sodium hyposulphite to a 5 to 10 per cent. soln. of uranyl sulphate until a precipitate begins to form. This is dissolved by adding a few drops of sulphuric acid, and the green soln. treated with its own vol. of 90 per cent. alcohol. The precipitate is washed with dil. aq. alcohol, dissolved in dil. sulphuric acid, and the soln. evaporated at a moderate heat—a 60 per cent. yield was obtained. The tetrahydrate appears as a pale green powder, or else in dark green, rhombic, bipyramidal crystals, which, according to W. F. Hillebrand and W. H. Melville, are isomorphous with the corresponding hydrate of thorium sulphate, $Th(SO_4)_2.4H_2O$, and have the axial ratios $a : b : c = 0.7563 : 1 : 0.3805$. L. Fernandes found that the tetrahydrates $U(SO_4)_2.4H_2O$ and $Zr(SO_4)_2.4H_2O$ are isomorphous and form mixed crystals over the range 99·14 to 10·3 per cent. of the zirconium salt; the crystals are also isomorphous with the corresponding compounds of cerium and thorium. J. J. Ebelmen added that the crystals are stable in air. V. Kohlschütter supposed that a second form of the tetrahydrate exists, $2U(SO_4)_2.8H_2O$, or $U_2(SO_4)_4.8H_2O$, which is produced by evaporating the soln. in dil. sulphuric acid; but F. Giolitti and G. Bucci could not verify this—*vide infra*.

N. A. Orloff obtained the *octohydrate*, $U(SO_4)_2.8H_2O$, by exposing to sunlight for some hours a soln. of uranyl sulphate in alcohol in the presence of some sulphuric acid; whilst F. Giolitti and G. Bucci recommended a soln. containing a gram of uranyl sulphate, 4 grms. of water, 2 grms. of 95 per cent. alcohol, and 0·863 grm. of sulphuric acid. G. N. Wyrouboff mixed uranyl sulphate or a soln. of uranosic oxide in conc. sulphuric acid with alcohol, and stirred the warm soln. for 2 or

3 hrs. The product is then dissolved in dil. sulphuric acid, and the uranous sulphate precipitated by alcohol. The product is heated to 200°, and when cold dissolved in water, and allowed to crystallize at ordinary temp. over sulphuric acid. The green crystals, said F. de la Provostaye, are stable in air. According to G. N. Wyrouboff, the monoclinic prisms are isomorphous with the crystals of the corresponding thorium sulphate, $Th(SO_4)_2.8H_2O$, and have the axial ratios $a : b : c = 0.7190 : 1 : 0.5692$, and $\beta = 93°\ 24'$. F. de la Provostaye thought the crystals were rhombic. R. J. Meyer and H. Nachod prepared the octohydrate by the electrolytic reduction of a standard soln. of uranyl sulphate containing 2 mols of conc. sulphuric acid per mol of the crystalline salt, and precipitating the soln. with alcohol, or else evaporating it at 75° or over sulphuric acid. If the soln. be evaporated at 93° to 95°, the tetrahydrate is formed, and it is also produced by gradually adding conc. sulphuric acid to the soln. between 0° and 70° until pre- cipitation ceases. The precipitation of the two hydrates from soln. thus depends on acidity. The octohydrate is irreversibly converted into the tetrahydrate at 68°; it is less soluble in $0.1N$-H_2SO_4 than in water; whilst below 55°, the tetra- hydrate is the more soluble, indicating the presence of complex ions. The solubility curves for the two hydrates in sulphuric acid soln.—*vide supra*, Fig. 12—intersect at 26°, but this is not a transition point; both hydrates are stable in soln. between 15° and 92°. The depression of the f.p. shows that the tetrahydrate has twice the mol. wt. of the octohydrate in $\frac{1}{8}N$- to $\frac{1}{32}N$-soln. in $0.1N$-H_2SO_4. For the octo- hydrate (mol. wt. 574) the mol. wts. are 66·2 and 51·0 respectively for soln. with 2·687 and 0·336 per cent. $U(SO_4)_2$; and for the tetrahydrate the mol. wts. are 119 and 78 respectively for soln. with 2·687 and 0·336 per cent. $U(SO_4)_2$.

F. Giolitti and G. Liberi reported the *pentahydrate*, $U(SO_4)_2.5H_2O$, as a pale green incrustation produced by the interaction of uranyl sulphate, water, 95 per cent. alcohol, and sulphuric acid, in the respective proportions by weight : 1, 4, 0·5, and 8 ; as well as the *hexahydrate*, $U(SO_4)_2.6H_2O$, in mammillary masses of pale green crystals, by the action of these constituents in the respective proportions by weight : 1, 4, 0·9, and 8 ; and 1, 4, 1·86, and 6. E. M. Péligot prepared crystals of the *ennea- hydrate*, $U(SO_4)_2.9H_2O$, by heating a mixture of uranium tetrachloride and sulphuric acid so as to drive off the hydrochloric acid, and allowing the green product to crystallize from an aq. soln. C. F. Rammelsberg obtained this hydrate by crystalliza- tion from a soln. of uranium dioxide in boiling conc. sulphuric acid, and he showed that the product obtained by E. M. Péligot, and thought to be the octohydrate, is really the enneahydrate. G. N. Wyrouboff added that the enneahydrate is formed only from a feeble acidified soln., and he obtained it by treating a cold soln. of uranyl sulphate with sodium thiosulphate, and dissolving the precipitate in dil. sulphuric acid. The soln. is treated with alcohol, and the precipitate dissolved in the least possible quantity of dil. sulphuric acid. The soln. is allowed to crystallize over sulphuric acid. The green, monoclinic prisms were found by C. F. Rammels- berg to be isomorphous with the corresponding thorium sulphate, $Th(SO_4)_2.9H_2O$, and to have the axial ratios $a : b : c = 0.5970 : 1 : 0.6555$, and $\beta = 97°\ 49'$. At first C. F. Rammelsberg mistook twinned monoclinic crystals for rhombic crystals. The (100)-cleavage is complete; and the (011)-cleavage is clear. G. Beck gave 4·60 for the sp. gr. of $U(SO_4)_2$, and 94·1 for the mol. vol.; he also gave 78 cals. for the heat of formation from the oxides.

G. N. Wyrouboff observed that the crystals of the enneahydrate lose a mol. of water when exposed to air; and C. F. Rammelsberg found that when the crystals are heated, water is slowly evolved—five-sixths of the total water is expelled at 200°; at 230°, 7 mols. are given off, and at a red-heat all the water along with some sulphuric acid is expelled; at a higher temp. all the sulphur trioxide is expelled and uranosic oxide remains. F. Giolitti and G. Bucci showed that the octohydrate loses a mol. of water when kept in a desiccator for 60 hrs., and when kept for 31 hrs., at a press. of 19 to 20 mm., 4 mols. of water are lost; and the remainder very slowly. The rate at which water is lost when the octohydrate is kept in a desiccator over

sulphuric acid furnishes a dehydration curve which has breaks corresponding with the *heptahydrate*, $U(SO_4)_2.7H_2O$; the *trihydrate*, $U(SO_4)_2.3H_2O$; and the *dihydrate*, $U(SO_4)_2.2H_2O$. When the octohydrate is heated in the absence of air, it passes into the tetrahydrate at about 90°, and into the anhydrous salt at about 300°, and at a higher temp. uranosic oxide is formed. At 100°, in a water-oven, the dihydrate is formed in 8 hrs.—and only another 0·52 per cent. of water is lost in 8 hrs. more. G. N. Wyrouboff found that the octohydrate loses 6½ mols. of water at 120° and 7½ at 200°. The salt always loses some sulphuric acid when the attempt is made to dehydrate it completely. F. Giolitti and G. Bucci found that the tetrahydrate quickly loses a mol. of water when under 19 to 20 mm. press., forming the trihydrate. The tetrahydrate behaves very like the octohydrate when it is heated. J. J. Ebelmen reported that normal uranyl sulphate is formed when hydrated uranous sulphate is heated in air. F. W. O. de Coninck observed that if uranous sulphate be gradually heated, the upper layer at a dull red-heat forms uranyl sulphate, while the layer underneath loses sulphur trioxide to form uranium dioxide, which passes partly into uranosic oxide and partly into what he regarded as uranium hemipentoxide. G. Beck gave 78 Cals. for the heat of formation of $U(SO_4)_2$. H. Becquerel studied the absorption spectrum. Uranous sulphate, even in acidic soln., is a strong reducing agent—*e.g.* it precipitates gold and silver from soln. of their salts—*vide supra*, uranous chloride. R. Luther and A. G. Michie found that the reducing action is accelerated catalytically by the presence of copper salts, and to a less degree by platinum black and by iron salts. The oxidation-reduction potential, taken as a measure of the oxidizing or reducing power of a soln., was determined by H. N. McCoy and H. H. Bunzel for a soln. of uranyl and uranous salts with an immersed platinum electrode, for $E=E_0+0.0298 \log_{10}([UO_2]/[U])E_0$ was found to be 0·615 volt, in the presence of $0.125M\text{-}H_2SO_4$, when the value for iron in neutral soln. is 0·987 volt, and for $0.05M\text{-}HCl$ soln., 0·984 volt. The lower value for uranium than for iron is in accord with the greater velocity of oxidation of uranous salts by air than is the case with ferrous salts. R. Luther and A. C. Michie found that a soln. of uranous and uranyl salts in sulphuric acid is 0·697 volt more positive than the normal hydrogen electrode—*vide supra*, uranium dioxide.

When the hydrated salt is heated in hydrogen, J. J. Ebelmen observed that it is converted into the dioxide. The tetra- and octohydrates, as indicated above, are stable in air, but the enneahydrate loses a mol. of water. The aq. soln. rapidly absorbs oxygen from the air, forming a yellow liquid. F. W. O. de Coninck, E. M. Péligot, J. J. Ebelmen, and V. Kohlschütter said that the tetrahydrate dissolves in water, but is quickly hydrolyzed, with the separation of a basic salt ; the degree of hydrolysis depends on the temp. ; if the mixture be exposed to air, the precipitate gradually passes into soln. as oxidation occurs. F. W. O. de Coninck said that 100 grms. of the sat. aq. soln. at 9·1° has 15·67 grms. $U(SO_4)_2$; at 11·3°, 15·96 grms. ; and at 13°, 16·02 grms. The soln. in darkness slowly deposits a basic salt. According to F. Giolitti and G. Bucci, the solubilities of the tetrahydrate and octohydrate expressed as S grms. of $U(SO_4)_2$ per 100 grms. of sat. soln. are :

S	12°	24°	37°	48·2°	63°	18°	25·5°	37°	48·2°	67°	93°
	16·0	9·8	8·3	8·1	7·3	10·7	13·32	19·98	28·72	36·8	63·2
		$U(SO_4)_2.4H_2O$						$U(SO_4)_2.8H_2O$			

Soln. of the octohydrate are stable between 18° and 105°. The separation of the tetrahydrate is very sluggish, and the exact temp. of the transformation has not been determined. At a temp. below 18° or 20° the octohydrate is the stable form in which uranous sulphate crystallizes from its aq. soln., because its solubility is then less than that of the tetrahydrate ; but above, say, 20° the octohydrate is the metastable form and the tetrahydrate the stable form. The transformation of the octohydrate into the tetrahydrate occurs between 68° and 87°, and hence takes place when the octohydrate is in a metastable state. Below 25° the sat. soln. is

liable to deposit a basic salt as a product of the hydrolysis. F. W. O. de Coninck found the sp. gr. of aq. soln. of uranous sulphate containing p per cent. of salt between 15·6° and 18·3° :

p .	. 1	2	4	6	8	10 per cent.
Sp. gr.	. 1·0058	1·0107	1·0218	1·0320	1·0429	1·0539

The soln. on electrolysis behaves like a soln. of uranyl sulphate ($q.v.$). E. M. Péligot found that when the normal salt is treated with an excess of water, **uranous oxysulphate,** $UOSO_4.2H_2O$, is formed as an insoluble precipitate. F. Giolitti and G. Bucci observed that when the octohydrate is treated with a large proportion of cold water, it is mostly dissolved, but about 25 per cent. is converted into a green powder of the oxysulphate—the amount so converted depends on the temp. If the octohydrate be acted upon by a small proportion of water, the basic salt at first formed slowly dissolves, forming a soln. of the normal salt. J. J. Ebelmen found that soln. of uranyl sulphate in dil. alcohol may deposit this basic salt when exposed to sunlight ; and a soln. of uranosic oxide in sulphuric acid may deposit this salt when it is boiled ; on cooling, however, the precipitate may re-dissolve. C. F. Rammelsberg obtained the same basic salt by adding ammonia, cautiously, to a soln. of the octohydrate—if too much ammonia be added, uranous hydroxide is formed. The *dihydrate* is a pale green powder, almost insoluble in water. J. J. Ebelmen found that with a large proportion of water, especially boiling water, the salt blackens and sulphuric acid is formed. F. Giolitti and G. Liberi also obtained the *pentahydrate*, $UOSO_4.5H_2O$, as a pale green powder. According to F. W. O. de Coninck, water can convert the normal octohydrate into **uranous hexoxytetrasulphate,** $U_5O_6(SO_4)_4.8H_2O$, or $UO_2.4UOSO_4.8H_2O$, which is less soluble in acids than is the case with the oxysulphate. F. Giolitti and G. Liberi reported **uranous trioxypentasulphate,** $U_4O_3(SO_4)_5.32H_2O$, or $3UOSO_4.U(SO_4)_2.$ $32H_2O$, as a pale green powder ; when the *dotricontahydrate* is dried in air, it furnishes the *icosihydrate*, $3UOSO_4.U(SO_4)_2.20H_2O$; the *pentadecahydrate*, $3UOSO_4.U(SO_4)_2.15H_2O$; and the *decahydrate*, $3UOSO_4.U(SO_4)_2.10H_2O$.

J. J. Ebelmen found the tetrahydrate to be very soluble in dil. hydrochloric acid, but much less soluble in the conc. acid. F. W. O. de Coninck observed that 100 parts of the acid diluted with four vols. of water dissolve 17·24 parts of the octohydrate at 9·2°, and 17·42 parts at 9·7° ; and that the sp. gr. of a soln. of p per cent. of the salt in hydrochloric acid of sp. gr. 1·046, between 16° and 18·4°, are as follow :

p .	. 1	2	3	4	5
Sp. gr.	. 1·0525	1·0572	1·0619	1·0667	1·0714

At 15·1°, 100 parts of hydrobromic acid, diluted with 4 vols. of water, dissolve 25 parts of the octohydrate. J. J. Ebelmen observed that the hydrated salt is freely soluble in dil. sulphuric, but less soluble in the conc. acid. R. J. Meyer and H. Nachod found for the solubility, S grms. of $U(SO_4)_2$ per 100 grms. of soln., of the octohydrate in $0·1N$-H_2SO_4 :

	15·5°	20·0°	30·4°	40·0°	60·0°	92·0°
S .	6·61	8·78	13·89	18·50	29·93	(6·61)

where the bracketed number refers to the formation of a less soluble polymer of the tetrahydrate. The solubility data for the tetrahydrate are :

	22·7°	25·0°	30·4°	40·0°	50·0°	80·0°
S .	13·68	12·62	10·92	8·98	8·32	6·93

The results are plotted in Fig. 13, where the dotted lines refer to the data of F. Giolitti and G. Bucci for aq. soln., Fig. 12. F. W. O. de Coninck found that 100 parts of sulphuric acid, diluted with 4 vols. of water, dissolve 15·5 parts of the

octohydrate at 10° ; and that soln. with p per cent. of the octohydrate in sulphuric acid of sp. gr. 1·14, between 17·4° and 18·7°, have the following sp. gr. :

p . .	1	2	3	4	5
Sp. gr. .	1·0525	1·0572	1·0619	1·0667	1·0714

V. Kohlschütter found that the soln. in dil. sulphuric acid is readily oxidized ; and F. Giolitti and G. Bucci observed that uranous sulphate dissolved in 10 per cent. sulphuric acid is not hydrolyzed. C. F. Rammelsberg showed that the soln. of the salt in very dil. sulphuric or hydrochloric acid becomes turbid when heated, but clarifies again on cooling. If conc. hydrochloric or sulphuric acid be added to the aq. soln., the salt is precipitated without having changed chemically. V. Kohlschütter poured a mush of uranous oxalate and conc. sulphuric acid into just enough water for dissolution, and found that the soln. solidifies in a short time, and after washing the product with absolute alcohol, by suction, there remained what appeared to be **uranous dihydro-pentasulphate,** $2U(SO_4)_2.H_2SO_4$, or $U_2H_2(SO_4)_5$. F. Giolitti and G. Bucci reported **uranous dihydrotrisulphate,** $U(SO_4)_2.H_2SO_4.10H_2O$, or $UH_2(SO_4)_3.10H_2O$, to be formed as a pale green powder, by the interaction, in sunlight, of a mixture of 42 grms. of uranyl sulphate, 168 grms. of water, 336 grms. of alcohol, and 41 grms. of sulphuric acid.

FIG. 13.—Solubility of Uranium Sulphate in Sulphuric Acid.

F. W. O. de Coninck reported that 100 parts of selenic acid of sp. gr. 1·4, diluted with 4 vols. of water, dissolve 21·46 parts of the salt at 10·7°, and 21·88 parts at 11·4° ; 100 parts of nitric acid, diluted with 4 vols. of water, dissolve 18·08 parts of the salt at 10·3°, and 18·5 parts at 11·2° ; 100 parts of 94 per cent. alcohol, diluted with 4 vols. of water, dissolve 12·19 parts of the salt at 9·6°, and 12·5 parts at 10·4° ; 100 parts of acetic acid, $CH_3COOH.H_2O$, diluted with 4 vols. of water, dissolve 24·4 parts of the salt at 15·5° ; and the solubility in glycol at 14·8° is 3·15 per cent. C. F. Rammelsberg's observation on the action of ammonia on the aq. soln. of the salt is indicated above. G. N. Wyrouboff found that the aq. soln. when treated with barium chloride and warmed gives a precipitate of a uranous salt and a liquid containing sulphuric acid, consequently he inferred that soln. contains a complex salt ; and this conclusion is in agreement with that of F. Giolitti and G. Bucci, cited above. F. W. O. de Coninck stated that platinum tetrachloride has no action on a very dil. soln. of the salt either in diffused daylight or in darkness ; but in direct sunlight the uranous sulphate is oxidized to uranyl sulphate, which then hydrolyzes to form a basic salt.

C. F. Rammelsberg reported that a soln. of ammonium and uranous sulphates furnishes dark green needles of **ammonium uranous tetrasulphate,** $(NH_4)_4U(SO_4)_4$. The salt is freely soluble in water ; and when heated, the soln. deposits a basic salt ; with potash-lye the salt gives off ammonia and forms uranous hydroxide. V. Kohlschütter reported **ammonium uranous hexasulphate,** $(NH_4)_6U(SO_4)_6.3H_2O$, to be formed by evaporating a soln. of uranous sulphate in a conc. soln. of ammonium sulphate mixed with just enough sulphuric acid to prevent turbidity. The dark green pyramids soon decompose ; **potassium uranous trisulphate,** $K_2U(SO_4)_3.2H_2O$, forms green plates. C. F. Rammelsberg represented the salt as a monohydrate and said that it is slightly soluble in water.

J. J. Ebelmen,[3] and A. von Unruh obtained anhydrous **uranyl sulphate,** $(UO_2)SO_4$, by heating one of the hydrates to 300°, and F. W. O. de Coninck, by heating the hydrate to 175°. According to A. C. Schultz-Sellack, the anhydrous salt is formed by evaporating a soln. of the salt in conc. sulphuric acid. The amber-yellow crystals do not effloresce ; they can be heated to dull redness without decomposition ; and, according to J. J. Ebelmen, when exposed to air they take

up about 3 mols. of water.   K. Brückner found that at a red-heat, in sulphur vapour, a mixture of uranous and uranosic oxides is formed.   J. A. Arfvedson dissolved uranosic oxide in hot, conc. sulphuric acid, diluted the soln. with water, and oxidized the solute by the addition of nitric acid.   J. J. Ebelmen evaporated a soln. of uranyl nitrate with sulphuric acid to dryness, expelled the excess of acid by heat, dissolved the residue in water, and evaporated the soln. to a syrupy consistency. When the soln. is allowed to stand for some time, it deposits crystals of the *trihydrate*, $(UO_2)SO_4.3H_2O$. F. W. O. de Coninck triturated uranyl sulphate with potassium or sodium hydrosulphate in a porcelain mortar, and as in some of W. Spring's experiments, the solids interact ; on extracting the product with water and crystallizing, the trihydrate is produced.   H. Lescoeur obtained the *monohydrate*, $(UO_2)SO_4.H_2O$, by adding an equal vol. of conc. sulphuric acid to a sat. soln. of uranyl sulphate ; and also by heating the trihydrate to 160°—*vide infra*— while F. W. O. de Coninck found that the trihydrate passes into the monohydrate between 110° and 115°.   The monohydrate takes up 2 mols. of water on exposure to air, reforming the trihydrate.   J. J. Ebelmen, and C. F. Bucholz represented the trihydrate by $(UO_2)SO_4.3\frac{1}{2}H_2O$, but E. M. Péligot showed that $(UO_2)SO_4.3H_2O$ is the correct formula.   A. Colani's results for the system $UO_2SO_4-H_2SO_4-H_2O$ at 25° are summarized in Fig. 14.   The curves are plotted from data of which the following are selected.   The concentrations are expressed in grams per 100 grms. of solution.

FIG. 14.—Equilibrium Curves of the Ternary System : $UO_2SO_4-H_2SO_4-H_2O$ at 25°.

UO_2SO_4	61·18	58·96	28·65	15·77	17·03	17·74	3·81	7·09
H_2SO_4 (free)	0	1·64	26·99	43·45	40·19	47·75	67·40	72·49

| | $UO_2SO_4.3H_2O$ | | $UO_2SO_4.2H_2O$ | | $UO_2SO_4.H_2SO_4.5H_2O$ | | |

UO_2SO_4	7·09	6·74	16·90	19·65	17·76	7·81	3·77
H_2SO_4 (free)	72·49	75·33	71·14	68·93	71·52	82·86	89·62

| | $UO_2SO_4.H_2SO_4.2H_2O$ | | $UO_2SO_4.H_2SO_4.\frac{1}{2}H_2O$ | | |

C. F. Bucholz described the crystals of the trihydrate as yellow prisms. P. F. Reinsch said that under the microscope the crystals appear dark bluish-yellow with a green shimmer, forming groups resembling asters.   F. W. Clarke gave 3·280 for the sp. gr. at 16·5°/4°.   G. Beck gave 5·24 for the sp. gr. and 69·9 for the mol. vol. of $UO_2(SO_4)$.   According to J. J. Ebelmen, the crystals of the trihydrate slowly lose about a mol. of water and effloresce on exposure to air ; they lose 2 mols. of water at 100°, and the third mol. begins to escape at 150°, and all is expelled at 300° ; and C. F. Bucholz added that when calcined in air, uranosic oxide is formed. F. W. O. de Coninck said that at 105° to 110°, 2 mols. of water are given off ; at a higher temp. a little sulphuric acid is lost ; at a dull red-heat some uranium trioxide is formed ; at bright redness, uranium dioxide ; and with continued calcination uranosic oxide is formed.   H. Lescoeur found that the vap. press., p mm., of $(UO_2)SO_4.nH_2O$, is :

n	Sat. soln.	2·75	2·3	1·7	1·3	1·1	1·0
p	10·8	11·0	9·8	9·7	9·2	4·5	<2

A. H. Pareau also made some observations on this subject.   G. Beck gave 50 Cals.

for the heat of formation. P. Pringsheim and M. Yost studied the Raman effect; and C. Ouellet, the photolysis of soln. containing uranyl sulphate. J. J. Ebelmen observed that when the salt is heated to redness in hydrogen, water and sulphur dioxide are first given off, then hydrogen sulphide and sulphur, and finally uranium dioxide, free from sulphur remains. F. W. O. de Coninck represented the reaction : $(UO_2)SO_4+2H_2=UO_2+SO_2+2H_2O$. The trihydrate is freely soluble in water. According to C. F. Bucholz, 100 parts of water at ordinary temp. dissolve 166 parts of salt, and boiling water, 222 parts of salt; whilst J. J. Ebelmen said that 100 parts of water at 21° dissolve 212·7 parts of salt, and boiling water, 357 parts; and F. W. O. de Coninck found that 100 parts of water at 13·2° dissolve 18·86 parts of salt; at 14·1°, 19·37 parts; at 15°, 20·20 parts; and at 15·5°, 20·40 parts. F. W. O. de Coninck found that aq. soln. of p per cent. of the salt, between 10° and 15·6° have the following sp. gr. :

p	.	. 1	2	4	6	8	10	12
Sp. gr.	.	. 1·0062	1·0113	1·0229	1·0338	1·0442	1·0557	1·0669

C. Dittrich measured the lowering of the f.p. of water, $\theta°$, of soln. with n mols of the salt per litre, and hence calculated the mol. wt. and degree of dissociation, a :

n	.	. 0·5	0·25	0·125	0·0625	0·03125
$\theta°$	.	. 0·968°	0·479°	0·256°	0·134°	0·074°
Mol. wt.	.	. 430·0	390·7	347·8	324·5	290·3°
a	.	. 0·14	0·06	0·05	0·13	0·26

These data show that in dil. soln. the sulphate is less ionized than the chloride or nitrate. F. W. O. de Coninck gave 5·5 Cals. for the heat of soln. at 17·3°; and J. Aloy, 5·1 Cals. for a mol of the trihydrate in 100 to 2500 mols of water at 18° to 20°. G. Beck gave 50 Cals. for the heat of formation from the oxide. F. W. O. de Coninck gave 1·365 for the index of refraction of an 8 per cent. soln., and 1·371 for a 10 per cent. soln. The absorption spectrum was studied by H. C. Jones and W. W. Strong; and the Becquerel effect, by I. Lifschitz and S. B. Hooghoudt. For the fluorescence, *vide supra*, the physical properties of uranium. H. M. Vernon estimated the degree of ionization from the colour. C. Dittrich gave for the conductivity, λ mho, of a soln. of an eq., *i.e.* half the mol UO_2SO_4, in v litres at 25° :

v	.	4	8	16	32	64	128	256	512	1024
λ'	.	17·1	20·5	25·5	32·0	41·5	53·2	67·7	85·2	103·4

As in the case of the chloride and nitrate, the difference $\lambda_{1024}-\lambda_{32}=71·4$ is unusually high. This is taken to mean that the ionization occurs in stages. C. Dittrich found that the migration velocity of the uranyl ion, in aq. soln. at 25°, is 56. The values for the eq. conductivity, λ, by H. C. Jones and co-workers, and the percentage ionization, a, are :

v	.	8	32	128	512	1024	2048	4096
λ { 35°	.	158·81	201·03	158·21	333·38	377·29	428·71	484·32
50°	.	179·79	223·69	288·77	381·83	436·95	512·04	597·28
65°	.	197·94	240·24	309·93	416·68	488·19	582·85	694·01
a { 35°	.	32·79	41·51	53·31	68·83	77·90	88·52	100·00
65°	.	28·52	34·62	44·66	60·04	70·34	83·98	100·00

The results of L. G. Winston and H. C. Jones between 0° and 35° are :

v	.	8	32	128	512	1024	2048	4096
λ { 0°	.	78·13	100·65	128·62	157·54	175·68	191·68	203·33
25°	.	120·82	156·80	203·02	257·69	296·95	332·57	373·65
35°	.	136·43	176·52	229·42	295·20	343·01	391·00	446·33
a { 0°	.	38·4	49·5	63·2	77·5	86·4	94·2	100·0
25°	.	32·3	42·0	54·3	69·0	79·5	89·0	100·0
35°	.	30·6	39·6	51·4	66·2	76·9	87·6	100·0

F. W. O. de Coninck found that when soln. of uranyl sulphate are electrolyzed in a U-tube, cooled by immersion in water, there is first deposited on the negative

electrode the yellow, hydrated oxide, $U_2O_3.2H_2O$, and finally a greenish precipitate consisting of the oxide and a small proportion of a basic sulphate.   A. S. Russell and D. C. Evans found that metals more electropositive than mercury, except cobalt, go into soln. as sulphates, without the accompaniment of mercury, when the amalgams are shaken with uranyl sulphate soln.   The order is not that of the electrode potentials of the metals in the free state, being: Zn, Mn, Cd, Tl, Sn, Pb, Cu, Cr, Fe, Bi, Co, Hg, Ni.   S. Freed and C. Kasper studied the magnetic susceptibility of the salt.

C. Dittrich found that the conductivity increases as the soln. ages with time, probably owing to hydrolysis.   Thus, L. R. Lecanu noted that the soln. is acidic to litmus.   L. Bruner studied the hydrolysis of the salt.   A number of basic salts has been reported.   N. Athanasesco reported **uranyl trioxysulphate,** $(UO_2)_4O_3SO_4.7H_2O$, as a dirty yellow mass of microscopic needles, to be formed by heating a 15 per cent. soln. of uranyl sulphate at 250°.   The water is expelled only at a high temp., and some of it is constitutional water.   J. M. Ordway found that the addition of barium carbonate to cold, aq. soln. of uranyl sulphate withdraws about two-thirds of the sulphate, and this corresponds with the formation of **uranyl dioxysulphate,** $(UO_2)_3O_2SO_4.nH_2O$.   Barium chloride, nitrate, or acetate also furnishes basic uranyl salts.   N. Athanasesco obtained the *dihydrate,* $(UO_2)_3O_2SO_4.2H_2O$, by heating a 3 per cent. aq. soln. of uranyl sulphate at 250°. The lemon-yellow, micro-crystalline powder is insoluble in and undecomposed by water.   The mineral **uraconite,** from Joachimsthal, Bohemia, described by J. F. Vogl as *Uranocker,* and by F. S. Beudant under the name *uraconite,* is an amorphous, lemon-yellow or orange, scaly or earthy, amorphous powder with a composition approximating the *tetradecahydrate,* $(UO_2)_3O_2SO_4.14H_2O$.   A. L. Fletcher noted that softening begins at 1050°, and fusion at 1070°.   J. M. Ordway treated an aq. soln. of uranyl sulphate with ammonia until half the acid radicle was neutralized, and obtained a white precipitate approximating **uranyl oxysulphate,** $(UO_2)_2OSO_4.nH_2O$.

A number of more or less basic sulphates has been described as minerals.   J. F. John described *Uranvitriol,* from Joachimsthal, and Johanngeorgenstadt, which W. Haidinger named **johannite**—after Archduke Johann of Austria.   C. U. Shepard also obtained it from Middletown, Connecticut.   The analysis reported by J. F. Vogl indicates 67·72 per cent. U_3O_8; 20·02, SO_3; 5·99, CuO; 0·20, FeO; and 5·59, H_2O.   Its colour is emerald-green or apple-green; the crystals are flattened, and are arranged in concentric druses or reniform masses.   The pleochroism is strong—*a* is colourless, *b* pale yellow, and *c* greenish-yellow or canary-yellow.   B. Jezek referred the mineral to the monoclinic system, but E. S. Larsen and H. Berman said the optical properties do not permit this orientation, since the extinction is not parallel to the *b*-axis.   E. S. Larsen and G. V. Brown described a hydrated uranium sulphate, containing some copper, iron, and sodium, from Gilpin County, Colorado, and Cornwall, England, and they called it *gilpinite.*   E. S. Larsen and H. Berman consider that the physical properties of gilpinite and johannite are so much alike that the two minerals can be considered to be the same species.   The chemical analyses of both agree better with $(Cu,Fe,Na_2)O.UO_3SO_3.4H_2O$ than with $CuO.3UO_3.3SO_3.4H_2O$; the minerals are triclinic, with the axial ratios $a:b:c=1·218:1:0·6736$, and $a=69° 24'$, $\beta=124° 56'$, and $\gamma=132° 56'$.   The optic axial angle $2V$ is nearly 90° for Na-light.   The mineral shows polysynthetic twinning in two directions, and resembles that of plagioclase. B. Jezek gave 3·307 for the sp. gr.   E. S. Larsen and H. Berman found that the indices of refraction are $a=1·572$ to $1·577$, $\beta=1·592$ to $1·597$, and $\gamma=1·611$ to $1·616$.   The subject was also discussed by E. S. Larsen and G. V. Brown.   The sp. gr. is 3·19, and the hardness 2·0 to 2·5.   H. Dauber described lemon-yellow crystals of a hydrated basic sulphate from Joachimsthal, Bohemia, containing 79·9 per cent. UO_3; 4·0, SO_3; and 14·3, H_2O.   A basic uranium sulphate from Joachimsthal, Bohemia, was called by J. F. John *verwitterter Uranvitriol;* by F. X. M. Zippe, *Uranblüthe;* by W. Haidinger, **zippeïte**—after F. X. M. Zippe; and by M. Adam, *dauberite*—after H. Dauber.   It occurs in sulphur-yellow, lemon-yellow, or orange-yellow delicate needles, acicular rosettes, or warty crusts of hardness 3. A. L. Fletcher gave 1250° for the fusion temp.   E. S. Larsen gave for the indices of refraction of zippeite $a=1·630$, and $\beta=1·70$; and $a=1·630$, $\beta=1·689$, and $\gamma=1·739$; and F. Slavik gave $\mu=1·634$ to $1·645$.   The analyses reported by J. F. Vogl have 62·04 to 67·86 per cent. U_3O_8; 13·06 to 17·36, SO_3; 0·17, Fe_2O_3; 0·61, CaO; and 15·23 to 17·69, H_2O.   J. F. Vogl described a basic sulphate from Joachimsthal, Bohemia, which J. D. Dana called **voglianite.**   It occurs in green, globular and nodular, earthy coatings and has the

analysis: 79·50 to 79·60, U_3O_8; 12·13 to 12·34, SO_3; 0·12 to 0·36, FeO; 2·24, CuO; 0·05 to 1·66, CaO; and 5·25 to 5·49, H_2O. The mineral was also described by F. Slavik.

F. W. O. de Coninck found that 100 parts of ordinary conc. hydrochloric acid at 128° dissolve 29·4 parts of uranyl sulphate, and at 13·6°, 30·76 parts; 100 parts of hydrobromic acid, of sp. gr. 1·21, at 11·2°, 16·4 parts; and at 12·9°, 16·9 parts; and 100 parts of sulphuric acid, of sp. gr. 1·138, at 12·7°, 23·25 parts, and at 14°, 24·39 parts. If the acid be diluted 1 : 4, 100 parts dissolve 27·02 parts of the salt at 15·3°, but the salt is less soluble in more conc. acid. He gave for the sp. gr. of p per cent. of uranyl sulphate in sulphuric acid of sp. gr. 1·168, between 20·6° and 22·7°, p=1, 1·1738; p=2, 1·1775; p=3, 1·1830; p=4, 1·1872; and p=5, 1·1918. J. J. Berzelius, and A. C. Schultz-Sellack obtained an acid salt corresponding with uranyl pyrosulphate from sulphuric acid soln.; and with a hot, conc. soln., J. J. Berzelius obtained uranyl trisulphate, $(UO_2)S_3O_{10}$. E. M. Péligot, and B. Drenckmann also obtained acid salts. G. N. Wyrouboff reported **uranyl dihydrotrisulphate,** $2(UO_2)SO_4.H_2SO_4.5H_2O$, to be formed by evaporating at 60° a soln. of a mol of uranyl sulphate in 5 mols of sulphuric acid. The pseudotetragonal cubes are very fluorescent, and deliquescent; and they lose 2 mols. of water at 110°. A. C. Schultz-Sellack, and E. M. Péligot obtained **uranyl dihydrosulphate,** $(UO_2)SO_4.H_2SO_4.$ $(UO_2)(HSO_4)_2$, by the slow evaporation of a soln. of uranyl sulphate in hot, moderately conc. sulphuric acid at about 200°. The greenish-yellow, fluorescent crystals are very deliquescent. F. W. O. de Coninck found that 100 parts of selenic acid, of sp. gr. 1·4, at 15·3°, dissolve 27·03 parts of uranyl sulphate.

A. von Unruh exposed anhydrous uranyl sulphate for 24 hrs. in an atm. of ammonia, and kept the product in a desiccator until it no longer smelt of ammonia, or until it had a constant weight; the yellow powder consists of **uranyl triammino-sulphate,** $(UO_2)SO_4.3NH_3$; if it be gently warmed, it forms **uranyl diammino-sulphate,** $(UO_2)SO_4.2NH_3$; and if it, or anhydrous uranyl sulphate, be digested with liquid ammonia, a deep orange powder of **uranyl tetramminosulphate,** $(UO_2)SO_4.4NH_3$, is formed. According to F. W. O. de Coninck, 100 parts of ordinary conc. nitric acid dissolve 8·93 parts at 10·8°, and at 12·3°, 9·26 parts of uranyl sulphate; if the acid be diluted with its own vol. of water, 100 parts dissolve 17·8 parts of salt at 15·4°, and 18·28 parts at 16·4°; while 100 parts of aqua regia, made from equal vols. of nitric and hydrochloric acids, at 15·4°, dissolve 17·86 parts of the salt.

According to C. F. Bucholz, 100 parts of absolute alcohol at ordinary temp. dissolve 4 parts of uranyl sulphate, and boiling alcohol, 5 parts; and F. W. O. de Coninck found that 100 parts of 85 per cent. alcohol dissolve 2·63 parts of the salt at 16·7°, and 2·59 parts at 15·8°. C. F. Bucholz, and J. J. Ebelmen observed that a soln. of uranyl sulphate mixed with alcohol and exposed to direct sunlight precipitates the whole of the uranium as uranous sulphate; F. Giolitti and G. Bucci obtained different products from mixed soln. of different proportions of uranyl sulphate, water, alcohol, and sulphuric acid; and F. W. O. de Coninck found that when aq. alcoholic soln. of uranyl sulphate are exposed to light, a mixture of uranous sulphate with a small quantity of basic uranyl sulphate is deposited. The filtrate, on exposure to violet or blue light, forms at first a hydrated uranosic oxide, and eventually the black oxide, U_4O_5. F. W. O. de Coninck said that uranyl sulphate is sparingly soluble in organic acids—*e.g.* conc. formic and acetic acids. W. T. Anderson and F. W. Robinson found that the photochemical decomposition of oxalic acid in the presence of a soln. of uranyl sulphate is a reaction of zero order, not greatly influenced by temp., and possesses the characteristics desired in an efficient chemical radiometer for use in the ultra-violet. The reaction was investigated by F. C. Hymas. R. H. Müller studied the decomposition of lactic acid in the presence of uranyl sulphate. The solubility in glycol is 1·15 per cent. at 15°. If uranyl sulphate is dissolved in a small quantity of water, mixed with an excess of ethylene glycol, and exposed to sunlight for 2 hrs., the liquid becomes quite green, and in $2\frac{1}{2}$ hrs. uranous sulphate is precipitated. In glycerol no such action takes place,

and even after fifteen months' exposure only a slight green coloration is obtained. This reaction serves to distinguish between ethylene glycol and glycerol. F. W. O. de Coninck observed that uranyl sulphate and calcium carbonate interact when covered with water, or when a mixture of the two salts is fused, triturated in a mortar, or compressed; and from 19·97 to 29·33 per cent. of calcium carbonate is converted into sulphate. For J. M. Ordway's observations on the action of barium carbonate, etc., *vide supra.* O. Hahn found that the precipitation of uranyl sulphate in the presence of uranium-X is not in harmony with K. Fajan's rule, but is in accord with the rule that an element is precipitated from its soln., however dilute, with a crystallizing precipitate when it is built into the crystal lattice of the precipitate and thus forms mixed crystals with the ions of the crystallizing precipitate. If this is not the case, the element remains in the filtrate, no matter how sparingly soluble its compound with the oppositely charged component of the lattice in the particular solvent may be. F. C. Hymas, W. T. Anderson and F. W. Robinson, and W. C. Pierce and co-workers studied the effect of uranyl sulphate on the photochemical decomposition of malonic, and oxalic acids. R. Rascanu prepared a complex with antipyrine.

J. A. Arfvedson, and E. M. Péligot evaporated a mixed soln. of uranyl and ammonium sulphates and obtained **ammonium uranyl disulphate,** $(NH_4)_2UO_2(SO_4)_2.2H_2O$, on evaporating the soln. for crystallization. C. F. Rammelsberg said that the crystals appear to be isomorphous with those of sodium manganese sulphate, and sodium magnesium sulphate. F. de la Provostaye described the crystals (of the dihydrate) as monoclinic prisms with the axial ratios $a:b:c=1·428:1:1·226$, and $\beta=102°$. P. Groth suggested that the compound may be triclinic and isomorphous with the $K_2Mn(SO_4)_2.2H_2O$ series, but G. Carobbi could find no evidence in support of this. H. Morton and H. C. Bolton said that the salt loses all its water and forms *ammonium diuranyl trisulphate,* $(NH_4)_2(UO_2)_2(SO_4)_3$, when it is heated; the transformation is attended by changes in the fluorescence and absorption spectra. At a higher temp., the salt passes into uranosic oxide. J. A. Arfvedson said that the salt is freely soluble in water; and E. M. Péligot, sparingly soluble. E. Rimbach, and F. W. O. de Coninck also prepared the

FIG. 15.—Equilibrium Diagram for the System: $(NH_4)_2SO_4$–UO_2SO_4–H_2O.

dihydrate, $(NH_4)_2(UO_2)(SO_4)_2.2H_2O$, by evaporating a soln. of eq. proportions of the component salts in vacuo. A. Colani obtained the dihydrate under the conditions indicated in Fig. 15.

F. W. Clarke found that the greenish, strongly fluorescent crystals have a sp. gr. 3·0131 at 21·5°/4°; they are stable in air and in water. J. Meyer and E. Kasper reported **ammonium uranyl disulphate,** $(NH_4)_4H_2[UO_4(SO_4)_2].3H_2O$, and **ammonium potassium uranyl trisulphate,** $(NH_4)_2K_4[UO_8(SO_4)_3]$; and E. Rimbach, unstable **ammonium uranyl trisulphate,** $(NH_4)_4(UO_2)(SO_4)_3.2H_2O$, to be formed like the corresponding potassium salt—*vide infra.* A. Colani obtained **ammonium diuranyl trisulphate,** $(NH_4)_2(UO_2)_2(SO_4)_3.5H_2O$, under the conditions indicated in Fig. 15. The following is a selection from the data :

UO$_2$SO$_4$.	61·18	61·28	61·32	47·25	35·70	16·46	10·00	1·89	0
(NH$_4$)$_2$SO$_4$	0	0·25	0·38	2·00	4·15	7·46	40·65	42·13	43·25

UO$_2$SO$_4$.3H$_2$O   (NH$_4$)$_2$(UO$_2$)(SO$_4$)$_2$.5H$_2$O   (NH$_4$)$_2$(UO$_2$)(SO$_4$)$_2$.2H$_2$O   (NH$_4$)$_2$SO$_4$

E. Rimbach, and H. Bürger obtained **hydroxylamine diuranyl trisulphate,** $(NH_4O)_2SO_4.2UO_2SO_4.5H_2O$, from a soln. of eq. proportions of the component

salts. The salt is difficult to crystallize on account of its large solubility. It can be obtained from aq. soln. in warty masses of crystals, or precipitated from its aq. soln. as a crystalline powder by means of alcohol. It gives no evidence of being decomposed by water. H. Grossmann and B. Schück prepared yellow, six-sided crystals of **ethylenediamine uranyl disulphate,** $C_2H_6(NH_2)_2(UO_2)(SO_4)_2.4H_2O$, which decompose at 285°; and G. Canneri obtained **guanidine uranyl disulphate,** $(C_5H_5N_3)_2.H_2SO_4.(UO_2)SO_4.6H_2O$.

F. W. O. de Coninck and E. Chauvenet prepared **lithium uranyl disulphate,** $Li_2(UO_2)(SO_4)_2.4H_2O$, by evaporating, at a low temp., an aq. soln. of equimolar proportions of the component salts; and F. W. O. de Coninck obtained **sodium uranyl disulphate,** $Na_2(UO_2)(SO_4)_2.3H_2O$, by well triturating a mixture of a mol of uranyl hydroxide with 2 mols of sodium hydrosulphate, and treating the product with water. A. Colani prepared this salt as well as **sodium uranyl trisulphate,** $Na_4(UO_2)(SO_4)_3.3H_2O$; and the equilibrium curves of the ternary system $Na_2SO_4-UO_2SO_4-H_2O$ at 25° are shown in Fig. 16. The following is a selection from the data:

UO_3SO_4 .	61·18	61·67	61·31	40·96	32·65	31·50	29·79	1·56	0
Na_2SO_4 .	0	1·32	6·03	14·56	25·10	25·53	25·72	20·41	20·70

$\underbrace{\hspace{3cm}}_{UO_2SO_4.3H_2O}$ $\underbrace{\hspace{3cm}}_{Na_2(UO_2)(SO_4)_2.3H_2O}$ $\underbrace{}_{Na_4(UO_2)(SO_4)_3.3H_2O}$ $\underbrace{}_{Na_2SO_4.10H_2O}$

J. A. Arfvedson, J. J. Berzelius, E. M. Péligot, J. J. Ebelmen, E. Rimbach, and H. Bürger prepared **potassium uranyl disulphate,** $K_2(UO_2)(SO_4)_2.2H_2O$, by

FIG. 16.—Equilibrium Diagram for the System: $Na_2SO_4-UO_2SO_4-H_2O$.

FIG. 17.—Equilibrium Diagram for the System: $UO_2SO_4-K_2SO_4-H_2O$.

crystallization from a soln. of the component salts; E. Rimbach, and H. Bürger, from a sulphuric acid soln. of potassium uranyl trisulphate (q.v.); B. Drenckmann, by evaporating a conc. sulphuric acid soln. of 2 mols of potassium hydrosulphate and a mol of uranyl nitrate until all the nitric acid is driven off, dissolving the residue in hot, conc. sulphuric acid, and cooling the soln. slowly—finally by a freezing mixture; and F. W. O. de Coninck, by triturating uranyl hydroxide with a large excess of potassium hydrosulphate. J. Meyer and E. Kasper gave the formula $KH_5[UO_4(SO_4)_2]$, as well as $K_2H_4[UO_4(SO_4)_2].2H_2O$, for their preparations. G. Carobbi found no evidence in support of P. Groth's suggestion that the crystals of the hexahydrate are triclinic and isomorphous with those of the $(Mg,Fe,Zn,Co,Ni)-(K,Rb,Cs,Tl,NH_4)_2(SO_4)_2.6H_2O$ series. A *trihydrate* was also formed by the process last described. F. de la Provostaye said that the lemon-yellow crystals of the *dihydrate* are monoclinic; they have a greenish fluorescence and are stable in air. A. Colani's study of the ternary system: $K_2SO_4-UO_2SO_4-H_2O$ at 25° is summarized in Fig. 17. The following is a selection from the data:

| UO_2SO_4 . | 61·18 | 61·25 | 61·50 | 59·29 | 39·73 | 9·91 | 2·39 | 0·91 | 0 |
| K_2SO_4 . | 0 | 0·23 | 0·45 | 0·51 | 1·77 | 2·69 | 11·17 | 10·69 | 10·40 |

$\underbrace{\qquad}_{UO_2SO_4.3H_2O}$ $\underbrace{\qquad}_{K_2(UO_2)_2(SO_4)_3.5H_2O}$ $\underbrace{\qquad}_{K_2(UO_2)(SO_4)_2.2H_2O}$ $\underbrace{\qquad}_{K_2SO_4}$

According to F. W. Clarke, the dihydrate has a sp. gr. 3·363 at 19·1°/4°. This salt is of historical interest, since in 1896 H. Becquerel first detected the phenomenon of radioactivity in the crystals of this salt. J. J. Ebelmen said that the dihydrate loses all its water at 120°, and J. J. Berzelius added that it fuses at a red-heat, and on cooling, it appears greenish-yellow, but, according to J. J. Ebelmen, the salt is not chemically changed. At 22°, 100 parts of water were found by J. J. Ebelmen to dissolve 11·11 parts of salt, and boiling water, 19·61 parts. According to E. Rimbach, and H. Bürger, 100 parts of soln. contain 10·41 parts of salt at 25°, and 23·13 parts at 70·5°; in both cases, soln. and solid have the same composition, and the salt can be recrystallized many times from water without perceptible change. J. J. Ebelmen found that both aq. ammonia and a soln. of ammonium sulphide precipitate hydrated uranium trioxide from the aq. soln. The precipitate is contaminated with adsorbed alkali. J. J. Berzelius found that alcohol does not dissolve the double salt, and precipitates it from its aq. soln. ; whilst J. A. Arfvedson added that alcohol extracts some uranyl sulphate from the double salt. According to E. Rimbach, a hot soln. of uranyl sulphate with an excess of potassium sulphate, say in the mol. proportion 1 : 3, furnishes crystals of **potassium uranyl trisulphate,** $K_4(UO_2)(SO_4)_3.2H_2O$, which are decomposed in aq. soln. into $K_4(UO_2)(SO_4)_3$ $\rightleftharpoons K_2SO_4 + K_2(UO_2)(SO_4)_2$. The equilibrium is displaced from right to left, and conversely with a falling temp. In sat. soln., the soln. is richer in potassium sulphate than the excess of solid. When the salt is recrystallized from a sulphuric acid soln., the decomposition is complete, and crystals of the disulphate are formed. A. Colani prepared **potassium diuranyl trisulphate,** $K_2(UO_2)_2(SO_4)_3.5H_2O$; and J. Meyer and E. Kasper, **potassium uranyl trisulphate,** $K_2H_4[UO_3(SO_4)_3].6H_2O$. E. Rimbach prepared crystals of **rubidium uranyl disulphate,** $Rb_2(UO_2)(SO_4)_2.2H_2O$, from a soln. of equimolar proportions of the component salts. The crystals resemble those of the potassium salt ; they can be recrystallized from aq. soln. ; but the salt is not so soluble as the corresponding potassium salt. E. Rimbach said that **rubidium uranyl trisulphate,** $Rb_4(UO_2)(SO_4)_3.2H_2O$, can be obtained like the corresponding potassium salt, but it is far less stable. J. O. Perrine observed no ultra-violet fluorescence in the X-rays. F. W. O. de Coninck prepared **cæsium uranyl disulphate,** $Cs_2(UO_2)(SO_4)_2.2H_2O$, as in the case of the corresponding sodium salt.

For **copper uranyl sulphate,** *vide supra,* Johannite. J. L. Smith reported what he regarded as a hydrated **calcium uranyl sulphate,** occurring as a mineral near Adrianople, Turkey, and at Joachimsthal, Bohemia. He called it **medjïdite—** after the Sultan Abdul Medjid. It occurs as a dark, amber-yellow incrustation on pitchblende. Its hardness is 2·5. A. Breithaupt also described nodular crusts of green acicular crystals associated with the pitchblende of Joachimsthal, Bohemia, and he called the mineral *uranochalzit,* or **uranochalcite.** Its hardness is 2·0 to 2·5 ; and its analysis : U_3O_8, 36·14 per cent. ; SO_3, 20·03 ; FeO, 0·14 ; CuO, 6·55 ; CaO, 10·10 ; and H_2O, 27·16. A. L. Fletcher gave 970° for the softening temp., and fusion occurs at 1110° to 1170°. The molten mineral attacks platinum, A. Weisbach described a uranium ochre occurring in yellow, flattened, acicular crystals as a velvety incrustation on the uraninite of Johanngeorgenstadt, Bohemia. The mineral is called **uranopilite.** The analysis corresponds with $CaO.8UO_3.2SO_3.25H_2O$. The sp. gr. is 3·75 to 3·97. F. W. O. de Coninck and E. Chauvenet obtained crystals of **magnesium uranyl disulphate,** $Mg(UO_2)(SO_4)_2.$ $5H_2O$, from a soln. of equimolar proportions of the component salts. According to M. Kohn, yellow rhombic crystals of **thallous uranyl disulphate,** $Tl_2(UO_2)(SO_4)_2.$ $3H_2O$, are produced when a hot, conc. soln. of equimolar proportions of the component salts in dil. sulphuric acid is allowed to cool. Supersaturated soln. of the

double salt are readily obtained. The water of crystallization is given off at 100°. J. O. Perrine observed no ultra-violet fluorescence in the X-rays.

§ 21. Uranium Carbonates

When an alkali carbonate is added to a soln. of a uranous salt, H. Rose,[1] C. F. Rammelsberg, E. M. Péligot, and J. L. C. Zimmermann observed that a whitish-green, voluminous precipitate is formed. It is sparingly soluble in a sat. soln. of an alkali carbonate, more soluble in a soln. of an alkali hydrocarbonate, and freely soluble in a soln. of ammonium carbonate. The precipitate is more or less hydrolyzed **uranous carbonate,** but C. F. Rammelsberg found that when washed and dried it is uranous hydroxide. The precipitate darkens when warmed owing to oxidation. The addition of ammonium carbonate to a uranous salt soln. was found by J. L. C. Zimmermann to give a whitish-green precipitate, soluble in excess. According to C. F. Rammelsberg, when the soln. of the precipitate in ammonium carbonate is allowed to evaporate, carbon dioxide is given off, and uranous hydroxide is first deposited, then ammonium diuranate; and J. A. Arfvedson found that when the soln. is heated, uranosic oxide free from carbonate is precipitated. Although uranous carbonate has not been prepared, the soln. of the precipitates just indicated in a soln. of ammonium carbonate is assumed to contain **ammonium uranous carbonate,** and in the case of the alkali carbonates, **alkali uranous carbonate.** E. M. Péligot obtained a precipitate of uranous hydroxide by adding calcium carbonate to a soln. of a uranous salt; and H. Rose, and J. L. C. Zimmermann found that all the uranium is so precipitated by the addition of barium carbonate.

J. J. Ebelmen found that alkali carbonates precipitate from soln. of uranyl salts a yellow alkali uranyl carbonate which is soluble in an excess of the precipitant, and it is more soluble in soln. of the alkali hydrocarbonates than in soln. of the normal carbonates. Alkali hydroxides precipitate alkali uranates from the soln. in alkali carbonates. A soln. of the precipitate produced by ammonium carbonate in an excess of that salt deposits, when boiled, hydrated uranium trioxide. J. N. von Fuchs observed that the addition of calcium carbonate to a soln. of a uranyl salt precipitates the uranium, and H. Rose found that with barium carbonate the precipitation is complete. J. M. Ordway made some observations on this subject —*vide supra*, basic uranyl sulphates. J. J. Ebelmen, and B. Drenckmann found that uranyl hydroxide attracts no carbon dioxide from atm. air. L. R. Lecanu, and E. M. Péligot believed that **uranyl carbonate,** $(UO_2)CO_3$, remained when ammonium uranyl carbonate is heated, but the observations of J. J. Ebelmen on the action of heat on this salt make this doubtful. According to W. T. Brande, hydrated uranium trioxide dissolves in an aq. soln. of carbon dioxide, and when the liquid is heated, the hydrated oxide is precipitated free from carbon dioxide. T. Parkman observed that the unwashed precipitate obtained by adding the least possible quantity of sodium carbonate to a soln. of uranyl nitrate contains $UO_3 : CO_2$ in the proportions $3 : 2$; and with sodium carbonate and soln. of uranyl sulphate, in the proportions $3 : 1$. These precipitates were supposed to be mixtures of alkali diuranate and uranyl carbonate. F. W. O. de Coninck added potassium carbonate to a soln. of uranyl nitrate, and obtained a precipitate with 17 per cent. of carbon dioxide, but after the precipitate had been washed it appeared to be a mixture of carbonate and oxide. K. Seubert and M. Elten obtained a complex basic salt whose analysis agreed with **uranyl decahydroxytri-**

carbonate, $5(UO_2)(OH)_2.3(UO_2)CO_3.6H_2O$, by mixing 10 grms. uranyl nitrate, with 5·7 grms. sodium carbonate in 20 c.c. of water. The orange precipitate was washed with alcohol. At the present time normal uranyl carbonate, $(UO_2)CO_3$, has not been isolated, and the different products which have been reported are stages in the hydrolysis : $UO_2CO_3+H_2O=UO_2(OH)_2+CO_2$. W. Marckwald found a kind of ochre as an alteration product of the uraninite of the Uruguru Mountains, East Africa, which he called **rutherfordite**—after E. Rutherford. For rutherfordite, *vide* **5**. 38, 3. The analysis corresponds with normal uranyl carbonate, $(UO_2)CO_3$. The yellow mineral is strongly radioactive, and has a sp. gr. 4·82.

Several complex uranyl carbonates have been obtained. J. J. Berzelius, L. R. Lecanu, E. M. Péligot, and W. Delffs obtained **ammonium uranyl tricarbonate,** $(NH_4)_4(UO_2)(CO_3)_3.2H_2O$, by dissolving ammonium diuranate in a warm, aq. soln. of ammonium carbonate and allowing the lemon-yellow filtrate to crystallize— assisted, maybe, by spontaneous evaporation. J. J. Ebelmen recommended digesting an excess of ammonium diuranate with a soln. of ammonium carbonate at 60° to 70°, filtering the soln. while warm, and allowing it to cool slowly. The undissolved ammonium uranate can be treated with the mother-liquor. E. Burcker added a mixture of aq. ammonia and ammonium carbonate to a soln. of uranyl nitrate until the precipitate first formed redissolved, and allowed the soln. to crystallize. According to F. Giolitti and V. Vecchiarelli, a soln. containing an excess of ammonia together with a mol of uranyl nitrate and 3 mols of ammonium carbonate deposits this salt in the form of lemon-yellow, transparent prisms which, according to F. de la Provostaye belong to the monoclinic system. W. Keferstein gave for the axial ratios $a:b:c=0.9635:1:0.8670$, and $\beta=99° 17'$; the (001)-cleavage is nearly complete. The sp. gr. is 2·773. According to J. J. Ebelmen, the salt can be preserved in stoppered bottles, but when opened, there is a smell of ammonium carbonate ; the salt is also stable in air containing a little vapour of ammonium carbonate, but in open air the salt is slowly decomposed and acquires an orange tinge. L. R. Lecanu, and E. M. Péligot thought that when the salt is heated uranyl carbonate is first formed, and then green uranosic oxide ; but J. J. Ebelmen showed that kept at 100° there is a considerable loss in weight in a few hours ; and between 200° and 250° there is a rapid evolution of water and ammonium carbonate, and the residue has an orange colour. The last portions of ammonium carbonate are expelled with difficulty, but if kept at 300° for a long time, brick-red uranium trioxide remains. If heated in a closed vessel, the salt leaves uranium dioxide, which is pyrophoric, taking fire in air as it oxidizes to green uranosic oxide. F. Giolitti and V. Vecchiarelli added that the salt loses ammonia at the ordinary temp., and more readily on heating to, say, 100°. The ratio $NH_3:CO_2$ always remains the same, 4 : 3, so that it must be assumed that the salt splits up completely with two parts $(UO_2)O$ and $CO_2.2(NH_4)_2CO_3$. The complex character of the salt is shown by the changes in the absorption spectrum which occur when ammonium carbonate is added to a soln. of uranyl nitrate ; by the cryoscopic measurements, which corre- spond with a decreasing mol. wt., ultimately reaching 90 ; and by the electrical conductivity, which also indicates an increasing and ultimately complete ionization. While J. J. Berzelius said that the salt is insoluble in water, J. J. Ebelmen found that 100 parts of water dissolve about 20 parts of the salt at 15°, and at 18·6° F. Giolitti and V. Vecchiarelli, 16·56 parts. The salt readily dissolves in a soln. of ammonium carbonate, and J. A. Arfvedson found that when the soln. is boiled, ammonium carbonate is given off, and the liquid becomes turbid as hydrated uranyl oxide is precipitated, but some uranium remains in soln., and, according to J. J. Ebel- men, and B. Drenckmann, the precipitate retains about 2 per cent. of adsorbed ammonia, but no carbon dioxide. E. M. Péligot supposed the precipitate to be ammonium diuranate. According to F. Giolitti and V. Vecchiarelli, the decom- position of the soln. by heat is very similar to that of the dry salt. The sat. soln., after being heated to 94° and cooled, deposits yellow needles of, probably, a basic ammonium uranyl carbonate ; and when the liquid is treated with ammonia,

I

ammonium uranate is precipitated. According to H. Schlundt and R. B. Moore, when an excess of hot $4N$-$(NH_4)_2CO_3$ is added to a nearly sat. soln. of uranyl nitrate, both uranium and uranium-X dissolve completely, but on cooling crystals of ammonium uranyl tricarbonate separate, while the whole of the uranium-X remains in soln. The radioactivity of the double carbonate increases after a time, a maximum being attained at the end of about twelve days. A similar increase takes place when the substance is gently heated. In both cases the increase in activity is accompanied by a slight deepening of the yellow colour of the crystals. The phenomenon appears to be due to the decomposition which the substance undergoes, the removal of ammonia, carbon dioxide, and water resulting in a diminution of the retardation of the particles which are emitted by the active element contained in the compound. The increase in the activity is proportional to the loss of weight, a similar effect being observed when thin layers of uranyl acetate and nitrate are gently heated. According to F. Giolitti and V. Vecchiarelli, when a conc. soln. of 5 mols. of ammonium carbonate is mixed with 2 mols. of uranyl nitrate, at 50° to 55°, the liquid, on cooling, deposits a bright yellow, crystalline mass of **ammonium diuranyl pentacarbonate**, $2(UO_2)CO_3.3(NH_4)_2CO_3.4H_2O$, which is soluble in water; this salt is said to be probably identical with one previously reported by E. M. Péligot. When alcohol is added to the mother-liquor, it deposits a bright yellow powder with a composition $(NH_4)_{18}(UO_2)_6(CO_3)_{17}.nH_2O$. It is soluble in water, but there is nothing to indicate that it is a chemical individual.

According to J. J. Ebelmen, uranyl hydroxide, precipitated by a soln. of sodium carbonate, dissolves in an excess of the precipitant, forming a yellow soln. containing a complex salt. If a soln. of sodium uranate in a warm, aq. soln. of sodium hydrocarbonate be evaporated, it furnishes a yellow crystalline crust of **sodium uranyl tricarbonate**, $Na_4(UO_2)(CO_3)_3$; and E. F. Anthon obtained it as a yellow crystalline powder by evaporating an aqua regia extract of pitchblende to dryness, extracting the product with water, adding an excess of sodium carbonate to the soln., and evaporating the liquid. W. Jani also obtained it by passing carbon dioxide through a soln. of sodium carbonate with sodium diuranate in suspension, and evaporating the filtered soln. E. F. Anthon found that the lemon-yellow powder loses water when heated, and it becomes brick-red and loses carbon dioxide before a red-heat is attained, but after heating for half an hour, at a red-heat, some carbonate still remains. W. Jani said that when the salt is heated, it acquires a pale brick-red colour, and water then extracts sodium carbonate from the cold mass, leaving a residue of sodium diuranate. E. F. Anthon reported that the salt dissolves slowly in water, and a soln., sat. at 15°, has a sp. gr. 1·61. According to J. Aloy, potassium uranate, and, according to J. J. Ebelmen, and M. E. Chevreul, precipitated uranyl hydroxide dissolve in an aq. soln. of potassium carbonate, but more readily in a soln. of the hydrocarbonate, forming a yellow liquid from which **potassium uranyl tricarbonate**, $K_4(UO_2)(CO_3)_3$, separates in yellow crystals or as a crystalline crust. J. J. Ebelmen, however, said that uranyl hydroxide precipitated by potash-lye is not soluble in a soln. of potassium carbonate, although it is readily dissolved by a soln. of the hydrocarbonate. J. Aloy also prepared this salt by treating a neutral soln. of a uranyl salt, say the acetate, with a small excess of potassium cyanide, dissolving the precipitate by adding sufficient potassium carbonate, and concentrating the soln. for crystallization. The lemon-yellow, hexagonal, bipyramidal crystals were found by J. Aloy to be stable in air. J. J. Ebelmen found that at 300° the salt is decomposed, forming orange-yellow potassium uranate; and, according to J. J. Berzelius, there remains a mixture of potassium diuranate and carbonate after the salt has been heated to redness. According to J. J. Ebelmen, 100 parts of water at 15° dissolve 7·4 parts of the salt, and more is dissolved at a high temp. One part of the salt in 333 parts of water gives a deep yellow soln.; or 1:1332-soln. is pale yellow; a 1:5328-soln. has a yellow tinge; and a 1:10656-soln. is colourless—the most dil. soln. is made turbid by potash-lye, and in a few hours deposits orange-yellow flakes of potassium diuranate. Boiling water

free from alkali, dissolves the salt with partial decomposition and the separation of potassium diuranate ; and a cold, very dil. soln. also deposits the uranate if an excess of potassium carbonate be not present. Potash-lye precipitates all the uranium in the soln. as potassium diuranate, even if a large excess of potassium carbonate be present. Acids, not in excess, produce the same yellow precipitate as is formed when potassium carbonate is added to a soln. of a uranyl salt. J. Aloy found that the salt is freely soluble in an aq. soln. of potassium carbonate ; and J. J. Ebelmen added that it is insoluble in alcohol. According to J. A. Hedvall, a large number of metallic ions give a precipitate with soln. of the alkali uranyl carbonates, but analytical results, the visible evolution of carbon dioxide, and the gradual colour change due to hydrolysis show that most of these products even shortly after precipitation cannot be regarded as definite compounds. Least hydrolysis occurs when the potassium uranyl carbonate in not too dilute a soln. is precipitated in the cold by addition of excess of the metallic salt soln. ; the precipitate is rapidly washed with water and allowed to dry in the air. Thus, *silver salts* give a yellow precipitate ; *mercurous salts*, a yellow precipitate—initially white and finally greyish-yellow ; *mercuric salts*, a red precipitate ; *cupric salts*, an apple-green precipitate, becoming yellowish-green ; *lead salts*, a white precipitate, becoming yellow ; *zinc and cadmium salts*, a pale yellow precipitate ; *manganous and aluminium salts*, no precipitate ; *ferrous salts*, a dark green precipitate ; *cobalt and nickel salts*, a pale yellow precipitate, becoming brownish-yellow ; *magnesium and calcium salts*, no precipitate ; *strontium salts*, a small, pale yellow precipitate ; and *barium salts*, a pale yellow precipitate.

    J. A. Hedvall prepared **silver uranyl carbonate,** $Ag_4(UO_2)(CO_3)_3$, in yellow flocks, which form a crystalline powder. It darkens in colour even when kept in the dark, owing to the uranium radiation. It begins to give off carbon dioxide at 145°. According to J. F. Vogl, a calcium uranyl carbonate occurs as an incrustation on the uraninite of Joachimsthal, Bohemia. According to analyses reported by J. F. Vogl, A. Schrauf, and H. von Foullon, its composition corresponds with **calcium uranyl tetracarbonate,** $Ca_2(UO_2)(CO_3)_4.10H_2O$. A. Weisbach called it flutherite, and A. Schrauf, **uranothallite.** The siskin-green mineral occurs in minute crystals, united in scaly or granular aggregates. A. Schrauf gave for the axial ratios of the rhombic crystals $a : b : c = 0.601 : 1 : 0.358$. The (100)-cleavage is imperfect. A. Brezina gave $0.9539 : 1 : 0.7826$ for the axial ratios, using better developed crystals than those used by A. Schrauf. The hardness is 2.5 to 3.0. J. L. Smith described another mineral from the uraninite deposits near Adrianople, Turkey, and he called it **liebigite**—after J. von Liebig. J. F. Vogl also described a similar mineral from Johanngeorgenstadt, Bohemia. The analysis corresponds with **calcium uranyl dicarbonate,** $Ca(UO_2)(CO_3)_2.20H_2O$. The apple-green, mamillary concretions or thin coatings show a cleavage in one direction. The hardness is 2.0 to 2.5. E. S. Larsen represented the formula of liebigite by $CaO.UO_3.2CO_2.20H_2O$, and he considered that liebigite and uranothallite are possibly the same mineral species. The optical axial angles $2E = 65°$; and $2V = 42°$; and the indices of refraction are $a = 1.500$, $\beta = 1.503$, and $\gamma = 1.537$. The cleavage is normal to a. In addition to the *icosihydrate*, liebigite, C. Blinkoff reported that the *decahydrate*, $CaCO_3.(UO_2)CO_3.10H_2O$, is formed by the action of carbon dioxide at 10 atm. press. on a suspension of 10 grms. of calcium uranate in 800 c.c. of water for two years. The compound is decomposed when boiled with water. If half the proportion of water is employed, the basic salt, **calcium tetrauranyl tricarbonate,** $2CaO.4UO_3.3CO_2.22H_2O$, is formed in pale yellow, tetragonal plates which are decomposed by water. A. Schrauf described a greenish or yellow mineral occurring in six-sided, rhombic plates on the uraninite of Joachimsthal, Bohemia. It was named **schröckingerite**—after Baron Schröckinger —and is regarded as a hydrated uranyl carbonate containing a little lime and sulphate. G. A. König described a canary-yellow incrustation on the granite at Franckford, Pennsylvania. He called it **randite**—after T. D. Rand. The analysis

is UO_3, 31·63 per cent.; CO_2, 29·34; CaO, 32·50; and H_2O, 6·53. J. F. Vogl described a **copper calcium uranyl carbonate** from the Elias mine, Joachimsthal, Bohemia. W. Haidinger called it **voglite**—after J. F. Vogl. It occurs in emerald-green or grass-green aggregates of rhomboidal scales. The analysis is UO_3, 37·00 per cent.; CO_2, 26·41; CaO, 14·09; CuO, 8·40; and H_2O, 13·90. C. Blinkoff reported **strontium diuranyl dicarbonate**, $SrO.2UO_3.2CO_2.10H_2O$, to be formed by treating a soln. of 10 grms. of uranyl nitrate with strontium hydroxide, suspending the washed precipitate in 200 c.c. of water, and leaving the mixture for a long time in contact with carbon dioxide under press.—*vide supra*, calcium uranyl carbonate. The salt is decomposed by boiling water. J. A. Hedvall prepared **barium uranyl carbonate**, $Ba_2(UO_2)(CO_3)_3.6H_2O$, in yellow microscopic plates, by the action of a barium salt on a soln. of potassium uranyl carbonate. It loses water slowly at ordinary temp., and more quickly at 50°, changing in colour from bright yellow to lemon-yellow. Above 350° much carbon dioxide is given off, and the colour becomes orange-yellow. C. Blinkoff obtained **barium diuranyl dicarbonate**, $BaO.2UO_3.2CO_2.5H_2O$, in a similar way. In addition to the *pentahydrate*, he obtained an *octohydrate* by using twice as much water for the preparation of the salt. H. Behrens and P. D. C. Kley obtained **thallous uranyl tricarbonate**, $Tl_4(UO_2)(CO_3)_3$, as a crystalline precipitate on adding thallous nitrate to an ammoniacal soln. of sodium uranyl carbonate. The crystalline precipitate is very sparingly soluble in water, so that the formation of this salt is recommended for the micro-detection of uranium—one part in 5000 can be so detected.

B. Menes prepared **ammonium uranium tetracarbonate**, $(NH_4)_2[U(CO_3)_4].6H_2O$, by adding uranyl sulphate to a warm, sat. soln. of ammonium carbonate through which carbon dioxide is passed. The *guanidinium salt*, $(CN_3H_6)_2[U(CO_3)_4].10H_2O$, was also prepared.

§ 22. Uranium Nitrates

J. J. Ebelmen,[1] and F. Isambert treated uranous oxide or hydroxide with silver nitrate, and obtained what was considered to be **uranous nitrate,** $U(NO_3)_4$, but the silver oxide which was formed oxidized the product to uranyl nitrate. J. Aloy and G. Auber obtained a green soln. by the action of sodium hydrosulphite on uranyl nitrate, but the uranous nitrate could not be isolated.

C. F. Bucholz,[2] H. Kuhn, H. Lescoeur, B. Drenckmann, L. R. Lecanu, and E. M. Péligot obtained **uranyl nitrate,** $(UO_2)(NO_3)_2.6H_2O$, by evaporating for crystallization a soln. of uranosic oxide or uranium trioxide in dil. nitric acid. F. Janda recommended an acid of sp. gr. 1·321. F. W. O. de Coninck obtained a soln. of the salt by the metathetical reaction between soln. of silver nitrate and uranyl chloride. T. J. Savery obtained a soln. as a product of the action of tin and nitric acid on uranyl phosphate or ammonium uranyl phosphate. The *hexahydrate* is obtained by crystallization from the aq. soln. The hexahydrate is the ordinary form which is understood when speaking of uranyl nitrate. The conditions of stability are indicated in Fig. 18. It is prepared directly from uranite, as indicated in connection with the extraction of uranium. The commercial salt generally contains small proportions of impurities—according to F. Giolitti and G. Tavanti, particularly alkali. Methods for the purification of the salt were given by J. Aloy, and F. W. O. de Coninck. C. Dittrich purified the salt by passing hydrogen sulphide into a soln. of the commercial salt; added ammonia and ammonium carbonate in excess to the filtrate, and then added ammonium sulphide. The uranyl salt soln. is evaporated from the precipitate, and the filtrate boiled with hydrochloric acid to remove carbon dioxide. Ammonia and ammonium sulphide are added to precipitate uranyl sulphide; the mixture is boiled for an hour. The black mixture of sulphur and uranium dioxide is washed first with warm water, and then with warm water containing some ammonium sulphide. The product is calcined in air, and the uranosic oxide dissolved in nitric acid, and the soln. crystallized. The salt is further purified by repeated crystallization, as recommended by H. N. McCoy and G. C. Ashman. F. E. E. Germann found that the heating and cooling curves of soln. of uranyl nitrate show the existence of this hydrate. It is ,formed spontaneously below −35°, and does not exist above −20°. A. Colani measured the solubility of uranyl nitrate in nitric acid, and expressing concentrations in grams per 100 grms. of soln., at 25°, obtained:

HNO_3	0	12·35	28·67	30·15	46·12	53·71	60·38	68·83
$UO_2(NO_3)_2$	56·08	40·36	29·65	37·90	37·18	27·49	23·65	22·49
		$6H_2O$			$3H_2O$		$2H_2O$	

The results are plotted in Fig. 18. In addition to the hexa- and dihydrates, the conditions of stability of the *trihydrate*, $UO_2(NO_3)_2.3H_2O$, are shown in the diagram. E. Kordes gave −18·1° for the eutectic temp. R. de Forcrand obtained indications of the existence of a *tetracosihydrate*, $(UO_2)(NO_3)_2.24H_2O$, in his study of the heating and cooling curves of sat. soln. F. W. O. de Coninck said that at 100° the hexahydrate passes into the *tetrahydrate*, $(UO_2)(NO_3)_2.4H_2O$, and that the tetrahydrate passes into the hexahydrate in moist air. H. Lescoeur found that the hexahydrate at 85° loses water and nitric acid, leaving a mixture of what is probably uranium trioxide and the trihydrate. E. M. Péligot found that the hexahydrate forms the trihydrate in vacuo. J. Aloy exposed the hexahydrate in vacuo or to a current of dry air at 0°; P. Lebeau dried the hexahydrate at ordinary temp. and press. in a desiccator over conc. sulphuric acid or calcium oxide for 5 or 6 days; and A. von Unruh heated the hexahydrate at 200° for some hours, and also passed a current of dry air over the addition product with ether. A. C. Schultz-Sellack reported that if a soln. of uranyl nitrate in nitric acid be evaporated and cooled, yellow fluorescent needles of the trihydrate are formed—the evaporation may be conducted in vacuo over conc. sulphuric acid, and potassium

hydroxide ; but B. Drenckmann said that the hexahydrate alone is formed under these conditions. A. Ditte, however, obtained the trihydrate from a soln. of uranyl nitrate in monohydrated nitric acid. G. N. Wyrouboff obtained the trihydrate by evaporating a neutral soln. at 65° and drying the crystals at the same temp. The trihydrate was found by G. N. Wyrouboff to furnish yellow triclinic crystals with the axial ratios $a : b : c = 1.7753 : 1 : 1.4104$, and $a = 85° 35'$, $\beta = 94° 12'$, and $\gamma = 81° 44'$. A. C. Schultz-Sellack said that the crystals do not effloresce in vacuo, but they take up water on exposure to air, passing into the hexahydrate. The m.p. is 120° ; A. F. Waseléeff gave 121·5°. A. Ditte found that 100 parts of monohydrated nitric acid dissolve 39 parts of the trihydrate at 14°. A. F. Waseléeff obtained the *dihydrate*, $(UO_2)(NO_3)_2.2H_2O$, by crystallization from conc. nitric acid of sp. gr. 1·502—with strongly acid soln. the hexahydrate is formed. M. Markétos also obtained it by dehydrating the hexahydrate in vacuo, and he said that the dihydrate is the equilibrium product under these conditions. P. Lebeau obtained the dihydrate by exposing to a current of dry air at ordinary temp. the crystals obtained by evaporating a soln. of the hexahydrate in ether, and dried with calcium nitrate. The conditions of stability are shown in Fig. 18. The pale yellow crystals of the

FIG. 18.—The Solubility of Uranyl Nitrate in Nitric Acid.

dihydrate were found by A. F. Waseléeff to be strongly fluorescent, and to melt at 179·3°. According to P. Lebeau, the salt decomposes in moist air at 115°, forming nitric acid and the hydrate $UO_3.2H_2O$. It dissolves in fuming nitric acid, and the soln. furnishes well-defined crystals. The percentage solubility in dry ether is 52·39 at 7° and 54·25 at 10°. A. F. Waseléeff, and P. Lebeau said that the *hemitrihydrate* probably does not exist. A. von Unruh reported a *monohydrate* to be formed in soln. by shaking the ethereal soln. for some hours with dry calcium chloride ; and J. Aloy, by heating the trihydrate at 100° in a current of dry air—if the temp. exceeds 100°, some nitrate is decomposed. R. de Forcrand's experiments on the dehydration of the hexahydrate give no indications of the existence of the monohydrate as a chemical individual. M. Markétos found that if the hexahydrate be heated to 170° to 180° in a current of carbon dioxide charged with the vapour of nitric acid, by bubbling the gas through nitric acid of sp. gr. 1·4 mixed with sulphuric acid of sp. gr. 1·843, a yellow powder of *anhydrous* uranyl nitrate is formed. A. von Unruh showed that the anhydrous salt cannot be obtained by heating the hexahydrate, or from the ether complex $(UO_2)(NO_3)_2.2(C_2H_5)_2O$, but an ethereal soln. can be obtained by treating an ethereal soln. of the trihydrate with sodium, calcium chloride, or copper sulphate. If the hexahydrate is employed, the water of crystallization settles to the bottom as a conc. aq. soln. of the uranyl salt, and if sodium is added, the alkali uranate is formed, and if calcium oxide is added, calcium uranate. If the hexahydrate be dissolved in amyl alcohol, and decanted from the aqueous layer which separates out, the anhydrous solid cannot be obtained from the amyl alcohol soln. either by evaporation or by keeping it in vacuo ; and when heated on an oil-bath, the amyl alcohol is oxidized to valeric acid, and uranosic oxide, and nitrous fumes are formed. According to P. Lebeau, the anhydrous salt is a yellow amorphous powder, readily soluble in water, and it reacts violently with ether. It decomposes at 200°, forming uranosic oxide and uranium trioxide. E. Späth obtained a different variety of the anhydrous salt by heating the dinitroxyl compound—*vide infra*—to 164°.

The hexahydrate forms lemon-yellow prisms having a greenish tinge. B. Drenckmann found that neutral soln. give tabular crystals, and acidic soln.,

prisms. F. de la Provostaye found that the rhombic bipyramidal crystals have the axial ratios $a:b:c=0\cdot8737:1:0\cdot6088$. Measurements were also reported by C. C. Haberle, J. Schabus, W. J. Grailich, and C. F. Rammelsberg. E. Quercigh studied the habit of the crystals separating from different solvents. L. Pauling and R. G. Dickinson found that the X-radiogram of the rhombic bipyramidal crystals of hexahydrated uranyl nitrate corresponds with a space-lattice having four mols of $UO_2(NO_3)_2.6H_2O$ per unit cell, with $a_{100}=13\cdot15$ A., $a_{010}=8\cdot2$ A., and $a_{001}=11\cdot42$ A. Observations on this subject were also made by G. L. Clark. J. Schabus said that the crystals are pleochroic, with a pale greenish-yellow, b greenish-yellow, and c lemon-yellow. A. des Cloizeaux gave for the optic axial angles with red and blue rays, $2E=68°\ 15'$ and $69°\ 15'$ respectively, and $2V=44°\ 5'$ and $44°\ 27'$ respectively; and W. J. Grailich gave $2E=68°\ 5'$ for red light. C. H. D. Bödeker gave $2\cdot807$ for the sp. gr. of the hexahydrate. A. F. Waseléeff gave for the sp. gr., D, of aq. soln. with p per cent. of the anhydrous nitrate :

p	.	.	2·80	10·92	20·05	29·77	39·73	49·92	54·77
D	.	.	1·33597	1·34417	1·35412	1·36758	1·38272	1·39889	1·41155
μ	.	.	1·0257	1·1035	1·1983	1·3247	1·4669	1·6506	1·7536

F. W. O. de Coninck also found for the sp. gr. of aq. soln. with :

p	.	1	2	4	6	8	10	12	14	16
D	.	1·0049	1·0096	1·0187	1·0281	1·0378	1·0462	1·0550	1·0643	1·0718

H. Lescoeur found the vap. press. of the hexahydrate to be negligible at 15°. At the m.p., 60°, the vap. press. of the sat. soln. is 12·2 mm.; that of the dry hexahydrate is 11·7 mm.; that of the molten hexahydrate, 11·8 mm.; and that of the 3·4 hydrate, less than 3 mm. E. Löwenstein found that with sulphuric acid of conc. C per cent. H_2SO_4, the losses in weight in t days, expressed in mols of water per mol of the hexahydrate, were :

C	.	30	40	50	60	70	80	90	97
t	.	10	10	10	20	20	30	30	30
Loss		0	0	0	2·94	2·99	3·97	4·01	4·00

With C below 20, the salt is hygroscopic. For the vap. press. of water corresponding with the different values of C, vide sulphuric acid. G. Tammann observed that the lowering of the vap. press. of water for soln. with 14·49, 34·62, and 46·40 grms. $UO_2(NO_3)_2$ per 100 grms. of water were, respectively, 13·1, 34·9, and 49·3 mm.

L. R. Lecanu observed that the hexahydrate remains unaltered in air between 15° and 20° ; but, added C. F. Bucholz, it effloresces to a yellow powder in a dry, warm atm. ; and E. M. Péligot observed that the trihydrate is formed when the salt is kept in vacuo. F. W. O. de Coninck said that if kept in air for 3 or 4 days the salt may have the eq. of 6 to 8 mols. of water. Various more or less discordant statements about the dehydration of the hexahydrate are indicated in connection with the reputed hydrates. C. F. Bucholz found that when the salt is heated, it melts in its water of crystallization, giving off water and acid. A. F. Waseléeff gave 60·2° for the m.p. of the salt, and J. M. Ordway, 59·5° ; at 118° the liquid begins to boil, when about 4 mols. of water and some acid are given off. When the liquid is cooled, E. M. Péligot observed that it forms transparent prisms, which, when exposed to air, rapidly absorb water and become opaque. At a higher temp. the molten liquid, said C. F. Bucholz, becomes reddish-yellow, ultimately forming uranosic oxide ; but, according to J. J. Berzelius, with the intermediate formation of a basic salt, and J. A. Arfvedson said that some uranyl nitrite is formed as the salt loses oxygen, and it decomposes into nitrogen oxides and uranosic oxide without the intermediate formation of uranium trioxide. F. W. O. de Coninck reported that 2 mols. of water are lost when the hexahydrate is kept for a few hours at 100° ; 2 mols. more water are lost between 115° and 130° ; and the remainder above 170°. The product fuses between 82° and 105° according to the proportion of contained water and loses some nitric acid ; at about 255° nitrous

fumes are given off, and at a higher temp. a red modification of uranium trioxide is formed (q.v.). The various reports on the dehydration phenomena are not all concordant. The observations of C. Dittrich on the lowering of the f.p., $\theta°$; the calculated mol. wt. when the theoretical value for $UO_2(NO_3)_2$ is 395·4; the factor i; and the degree of ionization, a, of n normal soln. of uranyl nitrate—$\frac{1}{4}UO_2(NO_3)_2$ per litre—are:

n	.	1	0·5	0·25	0·125	0·0625
θ	.	2·967°	1·339°	0·646°	0·329°	0·168°
Mol. wt.		153·4	151·6	148·9	142·5	137·8
i	.	2·57	2·60	2·65	2·77	2·87
a	.	0·78	0·80	0·82	0·88	0·94

Consequently the nitrate is almost completely ionized in $\frac{1}{16}N$-soln. F. W. O. de Coninck gave 0·946 for the sp. ht. of a 10 per cent. soln.; and C. Dittrich found the sp. ht. of $\frac{1}{2}N$- and $\frac{1}{4}N$-soln. of uranyl nitrate to be respectively 0·892 and 0·956. R. de Forcrand gave for the heat of formation of uranyl nitrate, $(UO_2,3O_2,N_2)_{solid}$ $=67·25$ Cals.; and for $(UO_2,3O_2,N_2,Aq.)=86·25$ Cals. R. de Forcrand gave for the heat of soln. of UO_3 in dil. nitric acid, 19·803 Cals.; $UO_3.H_2O$, 14·846 Cals.; and $UO_3.2H_2O$, 12·375 Cals. J. Aloy gave —3·7 Cals. for the heat of soln. of a mol of the trihydrate in 1000 to 2500 mols of water at 18° to 20°; and F. W. O. de Coninck —3·8 Cals. for the heat of soln. of the trihydrate in water at 17° to 18°. R. de Forcrand also gave for the heats of hydration for the solid hydrates from solid, liquid, and gaseous water: $UO_2(NO_3)_2 \rightarrow UO_2(NO_3)_2.H_2O+5·70$, 7·13, and 16·79 Cals. respectively; $UO_2(NO_3)_2.H_2O \rightarrow UO_2(NO_3)_2.2H_2O+5·39$, 6·82, and 16·48 Cals. respectively; $UO_2(NO_3)_2.2H_2O \rightarrow UO_2(NO_3)_2.3H_2O+2·27$, 3·70, and 13·36 Cals. respectively; and $\frac{1}{4}UO_2(NO_3)_2.3H_2O \rightarrow \frac{1}{4}UO_2(NO_3)_2.6H_2O+0·94$, 2·27, and 11·93 respectively. The subject was discussed by W. Biltz. R. de Forcrand, and M. Markétos also gave for the heats of soln., Q_s, of the anhydrous salt and its hydrates, $UO_2(NO_3)_2.nH_2O$:

n	.	.	.	0	1	2	3	6
Q_s { R. de Forcrand .				19·00	11·87	5·05	1·35	—5·45 Cals.
M. Markétos .				16·00	—	5·42	2·00	—4·76 Cals.

The optical character of the crystals of the hexahydrate is positive. V. von Lang gave for the mean index of refraction $\beta=1·4950$ for red, 1·4967 for yellow, 1·4991 for green, and 1·5023 for blue light. F. W. O. de Coninck gave $\mu=1·338$, 1·348, and 1·364 for the indices of refraction of 8, 10, and 12 per cent. soln. respectively. A. F. Waseléeff's measurements of μ at 17°/17° are indicated above. The absorption and fluorescence spectra were described by E. Hagenbach, H. Becquerel, H. C. Jones and W. W. Strong, etc.—vide supra, the physical properties of uranium. The absorption spectrum of aq. soln. was examined by E. L. Nichols and E. Merritt at temp. between 20° and —185°, and various changes were observed. H. L. Howes found that the spectra of aq. soln. showed the results indicated in Fig. 19. F. E. E. Germann explained the results by assuming that they are produced by the hexa- and tetracosihydrates and various mixtures of the two dependent on the conc. of the soln. and on the rate of cooling. J. C. Ghosh and B. N. Mitter also studied this subject—vide supra. V. R. von Kurelec examined the spectrum in various non-aqueous solvents; and B. K. Mukerji and N. R. Dhar, the photosensitization of aq. soln. H. M. Vernon estimated the ionization from the colour.

FIG. 19.—Absorption Spectra of Aqueous Solutions of Uranyl Nitrate.

J. Becquerel observed that the greenish-yellow fluorescence of the nitrate does not increase as the temp. is lowered to —190°; the converse statement applies to most fluorescent substances. A. Bornträger found that the dry crystals become luminescent when rubbed with the hand. A. S. Herschel found that the crystals exhibit a greenish-yellow triboluminescence, for they emit flashes of light when mechanically shaken or crushed; W. N. Iwanoff also noticed that slight detonations occurred when some crystals which had been kept in a stoppered bottle in the dark for three years were being weighed out. L. W. Andrews also noticed the detonation of some crystals in which the water of crystallization had been replaced by ether. W. Eichhorn observed the triboluminescence but no detonations when old crystals were shaken in a flask. A. Müller obtained only mild detonations in the case of a few specimens crystallized from ether, never when crystallized from water or prepared in the absence of free nitric acid; and he assumed that the effect may be due to the decomposition of an unstable compound of a lower oxide of nitrogen with a uranium-ether addition compound. X-rays had no perceptible effect on the crystallization of uranyl nitrate. J. A. Siemssen observed that a specimen of uranyl nitrate kept for 21 years in a stoppered bottle showed only a feeble triboluminescence in comparison with the effect produced by other specimens; and a specimen of sodium uranate which was not triboluminescent furnished uranyl nitrate with a fairly strong triboluminescence. H. Longchambon found that the spectrum of the triboluminescence of uranyl nitrate is the line spectrum of nitrogen complicated by the secondary effects of fluorescence.

G. L. Clark, and L. Pauling and R. G. Dickinson examined the action of secondary L-rays of uranium. E. K. Rideal and R. G. W. Norrish found that uranyl nitrate soln. have different potentials in light and in darkness. E. Shpolsky observed that the presence of uranyl nitrate or acetate inhibits the photochemical reaction in Eder's soln. H. Greinacher showed that the raising of the temp. by the radioactive transformations of the uranium, etc., amounts to $0.01°$—$vide$ radioactivity. J. Korczyn discussed the β-rays of the salt; J. C. Jacobsen, the action of γ-rays on the salt; and D. M. Bose and H. G. Bhar, the magnetic susceptibility.

According to F. W. O. de Coninck, aq. soln. of uranyl nitrate undergo photolysis, being slowly decomposed by diffused sunlight; but if the soln. are acidified by hydrochloric or acetic acid, they are very stable. Soln. of uranyl nitrate in commercial methyl or ethyl alcohol are readily decomposed by diffused sunlight, and a black uranium oxide is deposited. As indicated in connection with the general physical properties of uranium, C. F. Bucholz observed that ethereal soln. are decomposed in sunlight, forming ethyl nitrate, uranosic oxide, and a green liquid. P. Chastaing noticed that while red light and yellow light are without action on the alcoholic soln., violet light at once reduces the uranyl salt, forming aldehyde and acetic acid. H. Fay observed that a soln. of tartaric acid and uranyl nitrate gradually assumes a deep green colour when exposed to sunlight, a light green salt of uncertain character being subsequently deposited; the production of the latter is greatly promoted by heat, but in no case has gas been evolved—$vide$ $supra$, the physical properties of uranium. H. M. Vernon attempted to estimate the degree of ionization from the change in the colour of the soln. when diluted with water, and when warmed.

C. Dittrich measured the electrical conductivity, λ, of aq. soln. of an eq. of uranyl nitrate—$\frac{1}{2}UO_2(NO_3)_2$—in v litres of water at $25°$, and found:

v .	4	8	16	32	64	128	256	512	1024	2048	4096
λ .	74·09	81·42	88·23	94·34	100·8	107·6	115·0	122·7	131·5	140·7	151·8

Measurements were also made at $25°$ by H. Ley, and L. G. Winston and H. C. Jones, whilst A. P. West and H. C. Jones, and S. F. Howard and H. C. Jones obtained for

higher temp. the following results for the conductivities, λ, and the computed percentage degrees of ionization, a :

v		4	8	32	128	512	1024	2048	4096
$\lambda \begin{cases} 35° \\ 50° \\ 65° \end{cases}$	.	157·89	177·97	216·65	249·88	285·11	304·61	318·91	349·78
	.	199·01	226·59	279·42	327·08	376·95	404·71	422·85	467·92
	.	245·03	277·69	345·77	406·32	476·52	514·08	538·35	596·77
$a \begin{cases} 35° \\ 65° \end{cases}$	.	45·14	50·88	61·94	71·44	81·51	87·09	91·17	100·00
	.	41·06	46·53	57·94	68·09	79·85	86·14	90·21	100·00

L. G. Winston and H. C. Jones obtained :

v		4	8	32	128	512	1024	2048	4096
$\lambda \begin{cases} 0° \\ 25° \\ 35° \end{cases}$	.	74·91	83·44	97·22	110·14	116·33	123·14	128·92	136·77
	.	132·91	150·57	180·64	207·89	224·95	241·47	255·38	274·50

	.	46·3	52·8	63·9	74·1	80·8	87·1	92·5	100·00

The value of $\lambda_{1024} - \lambda_{32}$ in C. Dittrich's measurements is 37·16. This difference is unusually high for a normal salt of a bivalent anion. This is attributed to hydrolytic changes. L. R. Lecanu noticed that the moist salt reddens blue litmus ; and C. Dittrich's observations on the effect of uranyl nitrate on the inversion of sugar show that the degree of hydrolysis of $\frac{1}{10}N$-soln. of uranyl nitrate at 65° is 0·0361, meaning that at this temp. 0·036 of each eq. of uranyl nitrate in soln. is hydrolyzed ; at lower temp. the degree of hydrolysis will be smaller. L. Bruner studied the hydrolysis of the salt. The conductivity curve in C. Dittrich's measurements does not approach a constant value with increasing dilution, as would be the case if the process of ionization were simply that symbolized : $UO_2(NO_3)_2 \rightleftharpoons UO_2^{\cdot\cdot} + 2NO_3'$, although L. Gomez showed by taking the difference between each value of λ and the next succeeding one at double the dilution, the difference decreases until the dilution $v=64$. From this point the difference increases progressively. This is attributed to the progressive ionization of the salt, in accord with $UO_2(NO_3)_2 \rightleftharpoons UO_2(NO_3)^{\cdot} + NO_3'$, followed by $UO_2(NO_3)^{\cdot} \rightleftharpoons UO_2^{\cdot\cdot} + NO_3'$, with hydrolysis when the dilution exceeds $v=64$. Again, by extrapolation of the cryoscopic data, indicated above, the apparent mol. wt. at infinite dilution is almost exactly one-third the real mol. wt. This is in agreement with the scheme : $UO_2(NO_3)_2 \rightleftharpoons UO_2^{\cdot\cdot} + 2NO_3'$. With increasing conc., the ratio of the apparent to the real mol. wt. approaches the value 2·5, so that even in conc. soln. the salt is ionized to a considerable extent, possibly in accord with the equation : $2UO_2(NO_3)_2 \rightleftharpoons U_2O_4^{\cdot\cdot\cdot\cdot} + 4NO_3'$. The values of the degree of ionization, calculated on the assumption that the salt is a simple ternary electrolyte, are thus uncertain. L. Gomez measured the transport numbers for the anions at conc. between 0·0024 and 0·074 mol per litre. The resulting curve is typical of that of a ternary electrolyte, and shows a minimum at a conc. of 0·015 mol per litre, indicating a maximum conc. of the $[UO_2(NO_3)]^{\cdot}$-ion. At conc. beyond 0·07 mol, the transport number approaches unity, and the metallic radicle now forms part of the anion. At conc. lower than 0·01 mol the presence of UO_2'' is indicated. The addition of ammonia to a uranyl salt soln. precipitated the compound $(NH_4)_2U_2O_7$. This indicates the probable presence of the anion U_2O_7'' in the soln. F. W. O. de Coninck and M. Camo found that a black pyrophoric oxide is a product of the electrolysis of a soln. of uranyl nitrate. C. A. Pierlé measured the potentials of various uranium oxides (q.v.) against soln. of uranyl nitrate. H. Stadelmann examined the deposits obtained by dipping a carbon and a metal rod, electrically connected, into a soln. of uranyl nitrate. S. Bodforss studied the electrometric titration of a soln. of a uranyl salt in the presence of acetic acid by a soln. of a phosphate ; in presence of a small amount of a quadrivalent uranium salt, the equilibrium $UO_2^{\cdot\cdot} + 4H^{\cdot} - 2\ominus \rightleftharpoons U^{\cdot\cdot\cdot\cdot} + 2H_2O$ is set up and the potential E

of the soln. with respect to a platinum electrode is given by the formula $E=E_0+RT/2F.\log_e[UO_2^{..}][H^.]^4/[U^{....}]$. If the hydrogen-ion concentration remains constant, the potential is altered only when an excess of uranyl salt has been added. I. Lifschitz and S. B. Hooghoudt studied the Becquerel effect with soln. of uranyl salts. V. von Lang observed that the dimagnetism of crystals of the hexahydrate is strongest parallel to the a-axis of the crystals, and weakest parallel to the b-axis.

V. N. Ipatéeff and B. Muromtzeff found that hydrogen at 250 atm. press. and at 200° to 300° gives UO_3, U_3O_8, or UO_2—according to temp.—when it acts on a soln. of uranyl nitrate. According to C. F. Bucholz, the hexahydrate deliquesces in a moist atm., and cold water dissolves about half its weight of the salt, forming a greenish-yellow soln. F. W. O. de Coninck obtained a similar result between 12·9° and 14·2°. A. F. Waseléeff found the solubility, S, in grams of the hexahydrate per 100 grms. of sat. soln. to be :

	−18·1°	−12·1°	−2·2°	0°	12·3°	25·6°	36·7°	45·2°	71·8°
S	54·9	58·0	62·1	63·0	67·4	72·8	78·1	83·0	86·3

The eutectic point is at −18·1° and corresponds with the ratio $UO_2(NO_3)_2 : 28·9H_2O$. The freezing points of soln., with S grms. of the hexahydrate per 100 grms. of soln., are as follow :

	−1·6°	−2·1°	−2·9°	−4·4°	−6·0°	−7·9°	−11·2	−18 1°
S	13·8	15·6	21·9	30·0	33·4	41·4	47·5	54·9

The curve for these results is the ice line, Fig. 20. The hydrolysis of the salt has just been discussed. J. J. Berzelius observed that when aq. soln. of uranyl nitrate are boiled, and the filtrate evaporated, there remains a sticky mass of a basic salt, **uranyl oxynitrate**, of unknown composition. J. M. Ordway said that half the ammonia required for precipitating the uranium can be added before precipitation begins, and the soln. may then contain a basic salt. G. Rousseau and G. Tite observed that if a soln. of uranyl nitrate be heated with marble in a sealed tube at 180° to 200° for 24 hrs., a yellow, microcrystalline, basic uranyl nitrate is formed. A. Ditte heated uranyl acetate with monohydrated nitric acid, and obtained a yellow crystalline powder supposed to be basic uranyl nitrate. It is insoluble in water. J. W. Thomas found that hydrogen chloride acts on the trihydrate with the evolution of heat, forming uranyl chloride, etc.

FIG. 20.—Solubility of Hexahydrated Uranium Nitrate.

F. W. O. de Coninck found that uranyl nitrate is soluble in hydrochloric acid. It is also soluble in hydrobromic acid, and soln. of 1, 2, 3, 4, and 5 per cent. of uranyl nitrate in hydrobromic acid, of sp. gr. 121, have the respective sp. gr. 1·2122, 1·2168, 1·2198, 1·2250, and 1·2305. Uranyl nitrate is freely soluble in sulphuric acid, and soln. of 1, 2, 3, 4, and 5 per cent. of the nitrate in sulphuric acid, of sp. gr. 1·138, have the respective sp. gr. 1·1427, 1·1450, 1·1511, 1·1540, and 1·1576. F. J. Faktor found that sodium thiosulphate precipitates uranyl thiosulphate from soln. of uranyl nitrate. H. Rose said that when the salt is mixed with ammonium chloride and heated, uranosic oxide is formed. A. von Unruh obtained **uranyl diamminonitrate,** $UO_2(NO_3)_2.2NH_3$, as a yellow amorphous powder, by keeping in vacuo the diammino-complex with ether, and by passing ammonia into a soln. of uranyl nitrate in amyl alcohol—freed from water by boiling. The yellow flakes can be dried in vacuo over sulphuric acid. If the diammine be kept in an atm. of ammonia, it forms **uranyl triamminonitrate,** $UO_2(NO_3)_2.3NH_3$; and if in liquid ammonia, **uranyl tetramminonitrate,** $UO_2(NO_3)_2.4NH_3$. When treated with hydrazine hydrate, R. Salvadori obtained hydrazine uranates (*q.v.*). C. C. Palit

and N. R. Dhar found that the presence of uranium nitrate favoured the dissolution of mercury in nitric acid.   T. Curtius and A. Darapsky found that sodium azide colours the soln. deep red, and after boiling some time uranyl hydroxide is deposited.   According to E. Späth, when 22·5 grms. of dihydrated uranyl nitrate are dissolved in 30 c.c. of fuming nitric acid of sp. gr. 1·52, and the well-cooled soln. treated with a mixture of 20 grms. of nitrogen pentoxide and an excess of liquid nitrogen peroxide—12 c.c.—a light yellow precipitate of **uranyl dinitroxylnitrate,** $UO_2(NO_3)_2.2NO_2$, is formed.   It is decomposed by water into uranyl nitrate and nitrogen peroxide ; and at 163° to 165° it forms anhydrous uranyl nitrate, not the same as that prepared by M. Markétos.   F. W. O. de Coninck found that soln. of 1, 2, 3, 4, and 5 per cent. of uranyl nitrate in nitric acid, of sp. gr. 1·053, have the respective sp. gr. 1·1585, 1·1614, 1·1663, 1·1698, and 1·1751.   J. J. Berzelius, J. J. Ebelmen, E. M. Péligot, B. Drenckmann, and A. C. Schultz-Sellack were unable to prepare an acid salt of uranyl nitrate.   L. R. Lecanu observed that the salt fuses when heated on charcoal, and then detonates like nitre.   E. V. Alexeevsky and A. I. Avgastinik studied the adsorption of soln. of uranyl nitrate by charcoal. C. F. Bucholz found that 100 parts of absolute ethyl alcohol dissolve 333 parts of uranyl nitrate ; and F. W. O. de Coninck observed that at 12·7° to 13°, 100 parts of ethyl alcohol dissolve 3·33 parts of the salt; whilst 100 parts of methyl alcohol dissolve 4·35 parts of nitrate at 10·6° to 11·5° ; and that soln. of 1, 2, 3, 4, and 5 per cent. of uranyl nitrate in methyl alcohol have the respective sp. gr. 0·8902, 0·8938, 0·9003, 0·9068, and 0·9108.   Uranyl nitrate is also soluble in propyl and isobutyl alcohols, but less soluble in amyl alcohol.   C. F. Bucholz found that uranyl nitrate is freely soluble in ether ; P. Misciattelli compared the solubilities of the thorium and uranium nitrates in ether ; and he studied the ternary system $UO_2(NO_3)_2-H_2O-(C_2H_5)_2O$ at 0° and 20°.   For the system at 0° (Fig. 21), with non-saturated soln., the compositions of the aq. and ethereal layers were :

Aqueous layer			Ethereal layer		
Ether	Water	Nitrate	Ether	Water	Nitrate
11·6	88·40	—	99·00	1.00	—
9·79	77·74	12·47	98·53	1·60	0·31
7·05	73·50	19·38	97·49	0·96	1·55
9·48	66·56	25·09	86·46	6·95	6·58
6·48	65·00	38·52	87·85	3·02	9·13
5·50	66·50	38·00	67·50	6·50	26·00

whilst the compositions of the saturated soln. were :

Aqueous layer			Ethereal layer			
Ether	Water	Nitrate	Ether	Water	Nitrate	Solid phase
—	—	—	78·00	—	22·00	$UO_2(NO_3)_2$
—	—	—	68·00	7·00	24·50	
4·15	47·47	48·38	45·15	10·29	44·56	
5·00	46·30	48·70	41·17	13·56	45·27	$UO_2(NO_3)_2.6H_2O$
—	30·60	69·40	—	—	—	

The results are summarized in Fig. 21 ; and those for 20° in Fig. 22.   O. Guempel also studied the ternary system : uranyl nitrate–ether–water; and F. W. O. de Coninck stated that 100 parts of ether dissolve 6·25 parts of the salt at 10·6° to 11·5° ; whilst 100 parts of acetone, at 11·9° to 12·2°, dissolve 1·6 parts of the salt ; 100 parts of formic acid, at 10·6° to 11·5°, 18·6 parts ; and 100 parts of acetic acid, at 10·6° to 11·5°, 5·43 parts.   Soln. of 1, 2, 3, 4, 5, 6, and 7 per cent. of uranyl nitrate in acetic acid, of sp. gr. 1·055, have the respective sp. gr. 1·0387, 1·0434, 1·0469, 1·0505, 1·0564, 1·0626, and 1·0662.   L. Vanino said that when solid uranyl nitrate is heated with acetic anhydride, nitrogen oxides are evolved and uranyl acetate is formed.   F. W. O. de Coninck found that uranyl nitrate is soluble in ethyl acetate, sparingly soluble in turpentine, and insoluble in petroleum and in the aromatic hydrocarbons—benzene, toluene, and xylene, as well as in carbon disulphide.

The data are not always concordant: thus, according to A. W. Postans, uranyl nitrate dissolves in all proportions in glycerol, whilst F. W. O. de Coninck said that it is insoluble. E. Shpolsky studied the inhibition of the photochemical reaction with Eder's soln.; and G. G. Rao and N. R. Dhar, the catalytic action in the photosynthesis of formaldehyde from alkali hydrocarbonates. W. Thomson and F. Lewis studied the action of uranium nitrate on indiarubber. R. Rascanu prepared complex salts with pyridine, quinoline, 2-methylquinoline, antipyrine, pyramidon, and phenacetin.

According to P. Jolibois and R. Bossuet, when sodium hydroxide is added to a dil. aq. soln. of uranyl nitrate, precipitation commences only when an equimolar proportion of the alkali has been added; from this stage up to the addition of two mols, a precipitate is obtained, and if this is filtered off and the filtrate is boiled, a further precipitate is deposited. Either precipitate contains 1·5 per cent. or more of sodium hydroxide, which is not removed by washing. If more than two mols of alkali are added, precipitation is complete and the precipitate contains still
FIGS. 21 and 22.—The Ternary System: $UO_2(NO_3)_2$–$(C_2H_5)_2O$–H_2O at 0° and 20°.

higher percentages of alkali. Radioactivity measurements on the different precipitates show that the intensity of radiation is proportional to the amount of radium present. The first precipitate which is formed contains a very important proportion of the uranium-X, the oxide of which is apparently less basic than that of uranium. D. I. Mendeléeff said that uranyl nitrate readily forms complex salts with the alkali nitrates; but, according to R. J. Meyer and F. Wendel, not with the nitrates of the bivalent metals, although A. Lancien reported unstable salts with the nitrates of cadmium, nickel, and rhodium.

R. J. Meyer and F. Wendel prepared **ammonium uranyl trinitrate,** $NH_4(UO_2)(NO_3)_3$, by crystallization from a soln. of equimolar proportions of the component nitrates in nitric acid of sp. gr. 1·4; or by crystallizing a soln. with an excess of potassium nitrate over sulphuric acid and potassium hydroxide. A. Colani found that the anhydrous salt separates from an equimolar mixture of the component nitrates in cold nitric acid of sp. gr. 1·33, and it is readily decomposed by water. The crystals were found by H. Steinmetz to be trigonal prisms, with the axial ratio $a : c = 1 : 10027$, and to have the (110)-cleavage perfect. The salt appears to be dimorphous, because E. Rimbach reported that the product obtained from a soln. of ammonium diuranate in an excess of conc. nitric acid contains both trigonal crystals and rhombic bipyramids, which, according to A. Sachs, have the axial ratios $a : b : c = 0·7003 : 1 : 1·1419$, with the optic axial angle $2H = 44° 41'$. The greenish-yellow crystals are hygroscopic. E. Rimbach's, and H. Bürger's observations on the solubility of the salt are summarized in Table II, which shows that at a low temp. the salt is decomposed in aq. soln., but as the temp. reaches about 60°, the salt is not decomposed. As a result, below 60°, the solid phase is a mixture of uranyl nitrate and of ammonium uranyl trinitrate, and the soln. contains more ammonium nitrate than corresponds with the double salt. A. Colani said that **ammonium uranyl tetranitrate,** $(NH_4)_2UO_2(NO_3)_4$, separates in slowly deliquescent crystals which are decomposed by water. H. Grossmann and B. Schück prepared

TABLE II.—THE SOLUBILITY OF THE AMMONIUM AND ALKALI URANYL TRINITRATES

Complex salt	Temp.	100 parts of solution contain				Atomic or mol. ratios in solution UO₂ : R : NO₃
		UO₂	R	NO₃	Total	
NH₄(UO₂)(NO₃)₃	0·5°	29·71	2·93	—	—	1 : 1·47 : 3·47

	80·0°	34·66	11·01	—	69·49	1 : 0·01 : 3·01
Cs(UO₂)(NO₃)₃	16·1°	31·39	6·59	—	55·39	1 : 0·43 : —

ethylenediamine uranyl nitrate, $C_2H_4(NH_2)_2.2HNO_3.UO_2(NO_3)_2.2H_2O$, in greenish-yellow, four-sided, columnar crystals, which melt at about 215° and are strongly fluorescent. The double uranyl nitrate acts on a photographic plate, whilst the double sulphate and chloride have no action on it; on the other hand, the electroscope is affected about equally by the nitrate and the sulphate. A. Colani said that the complex nitrates of uranyl and potassium and sodium nitrates do not crystallize from aq. soln. in the cold. R. J. Meyer and F. Wendel were unable to prepare *lithium uranyl nitrate* or *sodium uranyl nitrate*; but they prepared **potassium uranyl trinitrate**, $K(UO_2)(NO_3)_3$, as in the case of the ammonium salt, from a soln. of the component salts. The rhombic, bipyramidal crystals were found by H. Steinmetz to have the axial ratios $a : b : c = 0.854 : 1 : 0.6792$, with a well-marked (010)-cleavage. The crystals of the salt prepared by E. Rimbach from a soln. of potassium diuranate in a large excess of nitric acid were also rhombic bipyramids, which, according to A. Sachs, have the axial ratios $a : b : c = 0.7015 : 1 : 1.1560$, and the optic axial angle $2H = 44° 34'$ for Na-light. The greenish-yellow fluorescent crystals are very hygroscopic. E. Rimbach, and H. Bürger found the solubilities indicated in Table II, and the results show that below 60° the salt is dissociated like the ammonium salt, but above that temp. the solid phase and solute have the same composition. W. Marckwald studied the radioactivity of the salt. R. J. Meyer and F. Wendel, and E. Rimbach prepared **rubidium uranyl trinitrate**, $Rb(UO_2)(NO_3)_3$, as in the case of the ammonium salt. A. Sachs gave for the axial ratio of the trigonal prisms, $a : c = 1 : 1.0074$, and $a = 96° 56'$. The (110)-cleavage is complete. The salt is less deliquescent than the potassium salt. The solubility data, Table II, by E. Rimbach, and H. Bürger show that somewhere below 80° the salt decomposes into its components, but above that temp. the solid phase and solute have the same composition. J. O. Perrine observed no ultra-violet fluorescence in the X-rays. E. Rimbach, H. Bürger, and R. J. Meyer and F. Wendel prepared **cæsium uranyl trinitrate**, $Cs(UO_2)(NO_3)_3$, as in the case of the ammonium salt. The trigonal crystals were found by A. Sachs to have the axial ratio $a : c = 1 : 1.0117$, and $a = 96° 48'$. They are isomorphous with those of the potassium salt. The effect of water is indicated in Table II. According to F. W. O. de Coninck, when silver nitrate is added to a soln. of uranyl chloride and the filtrate evaporated to dryness, there remains **silver uranyl nitrate**, mixed with

uranyl nitrate, and a red basic nitrate. J. O. Perrine observed no ultra-violet fluorescence in the X-rays. A. Lancien obtained **cadmium uranyl nitrate**, $Cd(UO_2)(NO_3)_4.30H_2O$, in yellow needles which lose 10 mols. of water in vacuo over sulphuric acid. J. O. Perrine observed no ultra-violet fluorescence with **mercury uranyl nitrate** in the X-rays. R. J. Meyer and F. Wendel prepared **thallous uranyl trinitrate**, $Tl(UO_2)(NO_3)_3$, by evaporating over sulphuric acid and potassium hydroxide a soln. of equimolar parts of the component nitrates in nitric acid of sp. gr. 1·4. The yellow crystals are not perceptibly fluorescent, and they are decomposed by moist air into their component salts. W. Marckwald found the radioactivity of the salt to be smaller than that of the potassium salt.

§ 23. The Uranium Phosphates

A. Colani,[1] and G. Werther prepared **uranous orthophosphate**, $U_3(PO_4)_4$, by treating a soln. of uranous tetrachloride with normal sodium phosphate. The voluminous precipitate, when washed, dried, and heated to redness in hydrogen chloride carried along by a current of carbon dioxide, forms a dark green powder consisting of minute crystals with hexagonal surfaces. This salt behaves chemically like other uranous phosphates, but is more readily attacked by acids, particularly nitric acid. P. Chastaing said that if an excess of a soln. of uranous chloride is treated with sodium metaphosphate, the green *trihydrate*, $U_3(PO_4)_4.3H_2O$, is formed. According to A. Colani, **uranous oxyphosphate**, $U_2O(PO_4)_2$, is obtained when uranyl orthophosphate or pyrophosphate is heated to dark redness in hydrogen; if the heating be continued too long, some phosphorus is lost as phosphine. The oxyphosphate is also obtained by heating the pyrophosphate in the hottest part of a porcelain oven. The former process yields a dark green, microcrystalline powder, the latter, larger crystals. The salt is easily attacked by boiling nitric acid. With alkali chlorides, in a dry atmosphere, it forms uranium dioxide and complex phosphates. P. Chastaing said that the green *trihydrate*, $U_2O(PO_4)_2.3H_2O$, is formed by precipitating a soln. of uranous chloride with normal sodium pyrophosphate, and the *tetrahydrate*, $U_2O(PO_4)_2.4H_2O$, by treating the soln. of uranous chloride with normal sodium orthophosphate. J. Aloy and G. Auber obtained uranous phosphates by the double decomposition of an alkali phosphate with a soln. of uranous sulphate, or by reducing uranyl phosphate with sodium hyposulphite. C. F. Rammelsberg, and J. Aloy said that an excess of sodium hypophosphate precipitates all the uranium from a soln. of uranous chloride as **uranous hydrophosphate**, $U(HPO_4)_2.2H_2O$. The product is very sparingly soluble in dil. hydrochloric acid, but freely soluble in the conc. acid, and the phosphate is re-precipitated on adding water. R. Arendt and W. Knop also obtained the *dihydrate* by treating a hydrochloric acid soln. of uranous chloride with phosphoric acid; and P. Chastaing, by adding an excess of sodium metaphosphate to a soln. of uranous chloride. C. F. Rammelsberg found that potash-lye extracts the phosphoric acid, but not so aq. ammonia. J. Aloy said that the precipitate from uranous oxalate is the *pentahydrate*, $U(HPO_4)_2.5H_2O$, or $UO_2.P_2O_5.6H_2O$, and it can be obtained in microscopic crystals stable in air, insoluble in sulphuric and hydrochloric acids of medium concentration, but freely soluble in conc. hydrochloric acid, forming a blue soln., and decomposed by alkali-lye, forming uranous hydroxide.

C. F. Rammelsberg obtained **uranous pyrophosphate,** $UP_2O_7.3H_2O$, by treating a soln. of uranous chloride with normal sodium pyrophosphate. The *trihydrate* loses all its water when heated in a current of carbon dioxide. A. Colani prepared it by reducing amorphous uranyl metaphosphate in hydrogen at a dull red-heat; the amorphous powder can be crystallized by heating it in a current of hydrogen chloride carried along by carbon dioxide. A. Colani also made the pyrophosphate by passing the vapour of phosphoryl monochloride in a current of carbon dioxide over uranous oxide at a red-heat—uranosic oxide can be used at a bright red-heat; it can also be obtained similarly from uranyl pyrophosphate or orthophosphate; a small amount of a volatile compound of uranium, phosphorus, and chlorine is formed. The pyrophosphate is also formed by heating one of the other uranous phosphates, with the exclusion of air, in a current of carbon dioxide, at the softening temp. of porcelain—with metaphosphate a part remains undecomposed. The pyrophosphate is also produced by heating a mixture of uranous metaphosphate with five times its weight of potassium chloride, at a dull red-heat, in a current of dry carbon dioxide, and afterwards washing the cold product to remove soluble salts.

P. Hautefeuille and J. Margottet prepared **uranous metaphosphate,** $U(PO_3)_4$, or $UO_2.2P_2O_5$, by melting uranium trioxide or uranyl metaphosphate with four times its weight of metaphosphoric acid—A. Colani used orthophosphoric acid; and K. R. Johnson dissolved uranyl sulphate in metaphosphoric acid at 316°. The emerald-green plates, said P. Hautefeuille and J. Margottet, are isomorphous with the metaphosphates of aluminium, chromium, and iron, and, according to A. Colani, with thorium metaphosphate, with which they form mixed crystals. The sp. gr. is 3·9, but K. R. Johnson gave 3·818 for the sp. gr. and 149 for the mol. vol. The salt does not melt in the blowpipe flame. The crystals are stable in air. A. Colani found that at a high temp., in hydrogen, uranium dioxide, phosphine, and phosphorus are formed. P. Hautefeuille and J. Margottet found that the salt is insoluble in water and acids, and A. Colani added that the metaphosphate is not dissolved by conc. and boiling hydrochloric, sulphuric, or nitric acid; if heated for 24 hrs. with 50 per cent. phosphoric acid in an evacuated and sealed glass tube, at 175° to 200°, a green soln. of a uranous salt is formed, and the soln. deposits fine green needles. With molten alkali hydroxides, oxygen is taken up from the atmosphere to form alkali phosphate and uranate; fused alkali carbonates in an atm. of carbon dioxide and at a red-heat form alkali phosphate and uranium dioxide—if air has access, the dioxide forms a uranate; and with fused alkali or alkaline earth chlorides, green crystalline products are formed. Boiling, conc. alkali-lye attacks the metaphosphate superficially, forming alkali phosphate and a protective black film of uranium dioxide.

According to A. Colani, when equal weights of sodium metaphosphate or, better, sodium pyrophosphate, and uranium dioxide are heated with a large excess of sodium chloride, or when equimolar parts of normal sodium and uranous pyrophosphates are heated with a large excess of sodium chloride, emerald-green crystals of **sodium uranous diphosphate,** $Na_2U(PO_4)_2$, are formed. This salt is also formed, with not such good results, by the general mode of preparation, namely, by heating an intimate mixture of the alkali phosphate with an excess of uranous oxide in a platinum Rose's crucible through which carbon dioxide is passed; the fused mixture is cooled very slowly, so as to cause the double phosphate to crystallize well and thus become separated from the excess of oxide used. The rhombic, bipyramidal crystals have the axial ratios $a : b : c = 0.6766 : 1 : 0.4006$. The salt is freely soluble in nitric acid, and the green liquid, when heated, or on standing at ordinary temp. for some time, becomes yellow and gives off nitrous fumes. It forms a yellow soln. with conc. hydrochloric acid which when treated with water gives a gelatinous precipitate of uranous phosphate. By heating a mixture of sodium uranous hexachloride with sodium pyrophosphate, or by heating sodium pyrophosphate with an excess of uranium tetrachloride, or by fusing uranium dioxide with sodium metaphosphate in the presence of sodium chloride, dark green crystals of **sodium uranous triphosphate,**

$NaU_2(PO_4)_3$, are formed. The monoclinic prisms have the axial ratios $a : b : c$ =2·5605 : 1 : 1·1918, and β=101° 3'. Again, if normal sodium pyrophosphate is fused with uranium dioxide, dark green rhombic crystals of **sodium uranous octo-phosphate**, $Na_{12}U_3(PO_4)_8$, are formed; they have the axial ratios $a : b : c$ =0·5758 : 1 : 0·2157. The general method of preparation just indicated, using potassium metaphosphate, furnishes green crystals of **potassium uranous di-phosphate**, $K_2U(PO_4)_2$. The rhombic crystals have the axial ratios $a : b : c$ =0·3711 : 1 : 0·3902. The chemical behaviour is the same as that of the corre-sponding sodium salt. If a mixture of potassium uranous hexachloride with the calculated quantity of normal potassium pyrophosphate be heated with an excess of potassium chloride, dark green, probably triclinic, plates of **potassium uranous triphosphate**, $KU_2(PO_4)_3$, are formed. Uranium dioxide heated with a mixture of normal potassium pyrophosphate and twice the weight of potassium chloride fur nishes dark green plates of **potassium uranous octophosphate**, $K_{12}U_3(PO_4)_8$. They are soluble in acids. By melting uranous metaphosphate with five times its weight of calcium chloride, green, pleochroic crystals of **calcium uranous diphosphate**, $CaU(PO_4)_2$, are formed. The monoclinic crystals have the axial ratio $a : b : c$ =1·508 : 1 : 1·124, and β=93° 29'. The green, pleochroic crystals of **strontium uranous diphosphate**, $SrU(PO_4)_2$, prepared in a similar manner, are rhombic and have the axial ratios $a : b : c$=1·474 : 1 : 1·165. The method employed for the calcium salt applies also to **barium uranous diphosphate**, $BaU(PO_4)_2$, which can also be prepared by fusing a mixture of one part of sodium uranous hexachloride, 3 parts of barium pyrophosphate, and 10 parts of anhydrous barium chloride. The salt appeared in thin green plates, too small for crystallographic measurement.

According to G. Werther,[2] when a soln. of 3 mols of uranyl nitrate, containing some free nitric acid, is mixed with a soln. of 2 mols of normal sodium phosphate, a yellow, pulverulent precipitate is produced from which acetic acid extracts only a little sodium uranyl acetate. The product is a hydrated mixture of normal **uranyl orthophosphate**, $(UO_2)_3(PO_4)_2.nH_2O$, with uranyl hydrophosphate, $UO_2(HPO_4).nH_2O$. If more sodium phosphate be added, the precipitate also contains sodium uranyl phosphate. The product forms a yellowish-green mass when ignited. F. A. Genth described a mineral from Mitchell Co., North Carolina, and he called it **phosphouranylite.** It occurs as a deep lemon-yellow, pulverulent incrustation on other uranium minerals; and the powder consists of microscopic rectangular plates. The analysis agrees with hydrated **uranyl orthophosphate,** $(UO_2)_3(PO_4)_2.6H_2O$, after deducting the 4·4 per cent. of lead oxide associated with the mineral.

The *trihydrate* of **uranyl hydrophosphate,** $UO_2(HPO_4).3H_2O$, was prepared by G. Werther, and H. Lienau by the addition of sodium dihydrophosphate to an acidic soln. of uranyl nitrate. It forms a sulphur-yellow, crystalline powder; and it can also be regarded as a pyro-salt, $(UO_2)_2P_2O_7.7H_2O$. Tetrahydrated uranyl pyro-phosphate, $(UO_2)_2P_2O_7.4H_2O$—*vide infra*—can be represented as a *hemitrihydrate* of uranyl hydrophosphate, namely, $2(UO_2)(HPO_4).3H_2O$. According to L. Bourgeois, if 5 grms. of ammonium dihydrophosphate and 18 grms. of uranyl nitrate be mixed in aq. soln., a precipitate is formed; this is washed by decantation, mixed with 500 grms. of water and enough hydrochloric acid to dissolve nearly all the precipitate, boiled, and the filtered liquid allowed to stand for some days. Yellow, tetragonal crystals of the *tetrahydrate*, $(UO_2)HPO_4.4H_2O$, are formed, having the axial ratio $a : c$=1 : 1·7284. H. Debray, and L. Bourgeois found that the salt becomes crystalline when heated in hydrogen chloride. This tetrahydrate also can be regarded as a pyro-salt, $(UO_2)_2P_2O_7.9H_2O$. A. Laugier, and G. Werther added phosphoric acid to a soln. of uranyl acetate, and obtained a crystalline precipitate of the *hemienneahydrate*, $(UO_2)(HPO_4).4\frac{1}{2}H_2O$; G. Werther also obtained it by treating a soln. of uranyl nitrate with sodium dihydrophosphate, or with insufficient normal sodium phosphate for the complete precipitation of the uranium; H. St. C. Deville added a soln. of acid calcium phosphate to an excess of uranyl nitrate soln.

at 50° to 60°; and W. Heintz found that a soln. of uranyl nitratophosphate in hot water gradually deposits the hemienneahydrate of uranyl hydrophosphate. The greenish-yellow salt forms microscopic, right-angled plates; it is insoluble in water, and the soln. in nitric acid furnishes a nitratophosphate. G. Werther said that the air-dried salt loses one-fifth of its total water at 60°; and W. Heintz, that it loses three-fifths of its total combined water at 110°. This hydrate can be regarded as a pyro-salt, $(UO_2)_2P_2O_7.10H_2O$. H. Lienau reported a *heptahydrate*, $(UO_2)(HPO_4).7H_2O$, by adding lithium dihydrophosphate to an acidic soln. of uranyl nitrate. It can be regarded as a pyro-salt, $(UO_2)P_2O_7.15H_2O$. G. Werther boiled uranium trioxide with a little phosphoric acid, and obtained the hemitri-hydrate, indicated above, as a yellow precipitate; while the mother-liquor, evaporated over sulphuric acid, slowly deposited lemon-yellow crystals of **uranyl dihydrophosphate,** $(UO_2)(H_2PO_4)_2.3H_2O$, a salt which can also be regarded as a pentahydrated metaphosphate, $UO_2(PO_3)_2.5H_2O$. When the salt is heated to 100°, it loses two-fifths of its water; at 110° to 120°, it loses 11·1 per cent.; and at 160°, 13·3 per cent., *i.e.* nearly four-fifths. The remaining water is given off at a red-heat. The salt is decomposed by water, forming an insoluble basic salt and a soluble acidic salt. It is soluble in phosphoric acid, forming a soln. which gives an ammonium salt when treated with ammonia. All the uranyl orthophosphates were found by G. Werther to decompose when melted with carbonized sodium potassium tartrate; and by H. Rose, with sodium carbonate and potassium cyanide, forming alkali phosphate and uranium dioxide.

According to R. Arendt and W. Knop, and A. Kitchin, **uranyl pyrophosphate,** $(UO_2)_2P_2O_7$, is formed by heating the hydrophosphate to redness. A. Girard obtained it by pouring an excess of a soln. of normal sodium pyrophosphate into an aq. soln. of uranyl nitrate—the precipitate gradually becomes crystalline—and heating the product to 100°. P. Chastaing also obtained it from the basic meta-phosphate by leaving it in contact with the mother-liquor for some time. The yellow precipitate loses 11 per cent. of water, *i.e.* 5 mols. at 100°. According to A. Girard, the pyrophosphate is insoluble in water, alcohol, and ether, but soluble in nitric acid, and the soln. when treated with alkali-lye gives a precipitate of the original salt. It dissolves in a soln. of sodium pyrophosphate, but not in a soln. of sodium hydrophosphate. P. Chastaing regarded the precipitate produced with a soln. of normal sodium pyrophosphate and a uranyl salt as a *tetrahydrate*, $(UO_2)_2P_2O_7.4H_2O$; and G. Werther obtained this hydrate as a pale yellow, amor-phous precipitate by treating uranium trioxide with dil. phosphoric acid, and washing the product with water. It loses about 3 mols. of water at 120°, and the remainder at a red-heat. It is dark yellow when hot, and pale yellow when cold. This salt can be regarded as hemitrihydrated uranyl hydrophosphate, $2(UO_2)(HPO_4).3H_2O$. Similarly, as indicated above, the *heptahydrate* of uranyl pyrophosphate is also $(UO_2)(HPO_4).3H_2O$; the *enneahydrate* is also $(UO_2)(HPO_4).4H_2O$; the *decahydrate* is also $(UO_2)(HPO_4).4\frac{1}{2}H_2O$; and the *pentadecahydrate* is also $(UO_2)(HPO_4).7H_2O$.

C. F. Rammelsberg boiled uranyl dihydrophosphate with nitric acid, and heated the product to redness. There remained **uranyl metaphosphate,** $UO_2(PO_3)_2$. P. Chastaing digested uranium trioxide and metaphosphoric acid in equimolar proportions, and obtained a yellow product which he regarded as a kind of basic salt, *uranyl oxymetaphosphate*, $4UO_3.3P_2O_5$; and the yellow precipitate pro-duced by the action of metaphosphoric acid on uranyl acetate he regarded as a decahydrate—possibly enneahydrate. It loses very little water at 100°, but at 110° it forms a heptahydrate. If allowed to stand in contact with its mother-liquor, it passes into the pyrophosphate, $(UO_2)_2P_2O_7.4H_2O$. According to J. B. Richter, if uranyl phosphate or carbonate be dissolved in phosphoric acid, and the soln. evaporated, an acidic salt is formed as an amorphous, sticky mass, and H. Rose obtained a similar product from a soln. of uranium trioxide in phos-phoric acid. P. Chastaing said that the mother-liquor remaining after the separa-

tion of $4UO_3.3P_2O_5$ from a soln. of uranium trioxide in phosphoric acid contains *uranyl tetraphosphate*, $UO_3.2P_2O_5$.

R. Arendt and W. Knop added uranyl acetate to a hot soln. of a phosphate and an excess of an ammonium salt, acidified with acetic acid, and obtained **ammonium uranyl phosphate.** H. Lienau prepared this salt, of the composition $(NH_4)(UO_2)PO_4.3H_2O$, by gradually adding a cold aq. soln. of 2 mols of ammonium dihydrophosphate and 2 mols of nitric acid to a soln. of 2 mols of uranyl nitrate. The crystalline precipitate is insoluble in water and acetic acid, but soluble in all the mineral acids, in oxalic acid, and in a soln. of alkali carbonate. A. Kitchin's method for the determination of uranyl salts is based on precipitation of the ammonium salt in the presence of acetic acid and ammonium acetate. The volumetric titration of phosphates with uranium salt soln. and potassium ferrocyanide as indicator was employed by C. Pincus—also by F. Sutton, H. Neubauer, R. Arendt and W. Knop, K. Broockmann, A. E. Haswell, C. Mohr, V. Edwards, G. Guérin, O. Abesser, W. Jani and M. Märcker, E. Kessel, C. Leconte, H. Rheineck, A. Pavec, W. Strecker and P. Schiffer, and A. Vozarik. In O. S. Pulman's method the uranium phosphate is reduced by zinc and acid to the uranous form, and titrated back to the uranyl salt by standard potassium permanganate. L. Barthe prepared **methylamine uranyl phosphate,** $(CH_3)NH_3(UO_2)PO_4$, as a pale yellow colloid, by saturating an aq. soln. of phosphoric acid with the amine, and adding uranyl acetate drop by drop. The precipitate, when dried in vacuo, becomes horny. It is stable, and is not decomposed at 100°. Similarly with **ethylamine uranyl phosphate,** $(C_2H_5)NH_3(UO_2)PO_4$, and with **trimethylamine uranyl phosphate,** $(CH_3)_3NH(UO_2)PO_4$. H. Lienau found that in attempting to prepare **lithium uranyl phosphate** by this process, heptahydrated uranyl hydrophosphate is formed, and the trihydrate was produced in attempting to prepare the **sodium uranyl phosphate.** G. Werther mixed soln. of uranyl nitrate and an excess of normal sodium phosphate, and obtained a dark yellow precipitate which dissolves in a large excess of the sodium phosphate soln., but it does not dissolve in water ; acetic acid extracts sodium diuranate. G. Werther represented the composition of the precipitate by $Na_2(UO_2)_5(PO_4)_4.6H_2O$, but seems to have regarded it as a mixture. L. Ouvrard found that fused normal sodium pyrophosphate or orthophosphate dissolves much uranium trioxide and obtained dendritic, yellow, monoclinic crystals of $Na_4(UO_2)(PO_4)_2$. G. G. Stokes examined the fluorescent properties of mixtures of uranyl and sodium phosphates. L. Ouvrard fused a mixture of uranium trioxide and normal potassium pyrophosphate, and obtained a sulphur-yellow powder of **potassium uranyl phosphate,** $K(UO_2)PO_4$, consisting of microscopic rhombic crystals. H. Grandeau prepared a similar salt by heating uranyl phosphate with an excess of potassium sulphate. H. Lienau obtained the *trihydrate,* $K(UO_2)PO_4.3H_2O$, by the method he employed for the ammonium salt. L. Ouvrard reported yellow prisms of $K_4(UO_2)(PO_4)_2$, to be formed by melting together uranium trioxide and normal potassium phosphate.

A. Rosenheim obtained **lithium uranyl pyrophosphate,** $Li_2[UO_2P_2O_7]$, as a crystalline precipitate by treating uranyl sulphate or nitrate with a conc. soln. of the alkali phosphate, and boiling the mixture. B. Menes prepared **lithium uranium pyrophosphate,** $Li_2H_2[U_2(P_2O_7)_3].30H_2O$, by treating a soln. of uranium sulphate with one of lithium pyrophosphate. J. Persoz treated a soln. of a uranyl salt with normal sodium pyrophosphate and obtained a precipitate soluble in excess; when the soln. is evaporated, it furnishes a gummy mass. G. Buchner found that the soln. gives no precipitate when treated with ammonium sulphide ; and that uranyl sulphide readily dissolves in a soln. of sodium pyrophosphate, and the soln. remains clear when boiled for a long time. All this points to the formation of a complex salt. L. Ouvrard prepared sulphur-yellow, monoclinic prisms of **sodium uranyl pyrophosphate,** $Na_2(UO_2)P_2O_7$, by fusing a mixture of uranium trioxide and sodium metaphosphate. According to P. Pascal, when a soln. of sodium pyrophosphate, saturated with uranyl pyrophosphate is treated with alcohol, a yellow

powder of the complex salt, $Na_6(UO_2)[(UO_2)_2(P_2O_7)_3].nH_2O$, is precipitated. It quickly passes into $Na_2(UO_2)_2P_2O_7.H_2O$, which is insoluble in water. The f.p. of uranyl pyrophosphate in sodium pyrophosphate rises to a maximum corresponding with $3Na_4P_2O_7.(UO_2)_2P_2O_7$, and then descends to a minimum at $2Na_4P_2O_7.(UO_2)_2P_2O_7$, up to which stage the characteristic reactions of uranyl salts are not obtainable. If this soln. is evaporated and the gummy residue treated with alcohol, a very soluble, hygroscopic powder having the constitution $Na_8[(UO_2)_2(P_2O_7)_3].6H_2O$ is obtained. A. Rosenheim obtained the sodium salt by the method he used for the lithium salt. B. Menes also prepared **sodium uranium pyrophosphate**, $Na_4[U_2(P_2O_7)_3].14H_2O$, by the action of a soln. of uranium sulphate on one of sodium pyrophosphate. No precipitates are obtained with ammonium and potassium salts. L. Ouvrard prepared **potassium uranyl pyrophosphate**, $K_2(UO_2)P_2O_7$, by melting uranium trioxide with potassium metaphosphate. The yellow, rhombic, dichroic, doubly refracting crystals have a sp. gr. 4·2 at 20°. A. Rosenheim and T. Triantaphyllides could not prepare complex uranic pyrophosphates analogous to those of chromic, molybdic, and manganic pyrophosphates.

The history of the mineral **torbernite**—*torberite, cupro-uranite, chalcolite, uranium-mica*, or *uranite*—has been previously discussed. The mineral is found at Joachimsthal and Zinnwald in Bohemia; at Johanngeorgenstadt, Eibenstock, and Schneeberg, in Saxony; at Reichenbach, Baden; at Tincroft, Wheal Buller, and other parts of Cornwall; Katanga, Belgian Congo; etc. Analyses by G. Werther, F. Pisani, A. H. Church, F. L. Hess, A. Pereira-Forjaz, V. Dürrfeld, W. Steinkuhler, C. Winkler, J. J. Berzelius, A. Frenzel, W. Gregor, M. H. Klaproth, R. Phillips, etc. The results correspond with **copper uranyl phosphate**, $Cu(UO_2)_2(PO_4)_2.8H_2O$. Y. Bucholz found that the Cornish mineral contains 12 not $8H_2O$. C. Winkler observed that arsenic acid may in part replace the phosphoric acid. F. Henrich, and J. Hoffmann discussed the radium content of the mineral. H. Debray obtained the octohydrate by adding uranyl nitrate to a soln. of copper carbonate in phosphoric acid, and allowing the liquid to stand for some time, best at 50° to 60°. Pale green plates are gradually deposited. Torbernite occurs in foliated or micaceous aggregates, and in square, thick or thin plates, and more rarely in pyramids. The colour is green in various shades which have been referred to as emerald-, leek-, apple-, siskin-, and grass-green. A. Schrauf gave for the axial ratio of the tetragonal crystals $a : c = 1 : 2.9361$; the (001)-cleavage is micaceous and perfect; the laminæ are brittle. A. F. Hallimond gave $1 : 2974$. The optical character is negative. T. L. Walker found that the corrosion figures have monoclinic symmetry; but F. Rinne obtained corrosion figures with cold acid, indicating normal tetragonal symmetry. The crystals were also described by A. Lévy, P. A. Dufrénoy, E. Mallard, J. F. L. Hausmann, R. P. Greg and W. G. Lettsom, F. Hessenberg, W. Phillips, N. von Kokscharoff, C. F. Naumann, A. Schrauf, T. L. Walker, F. Rinne, and A. F. Hallimond. A. Breithaupt said that the sp. gr. ranges from 3·329 to 3·372. In general, the sp. gr. of torbernite ranges from 3·33 to 3·60; and the hardness, from 2·0 to 2·5. N. L. Bowen found torbernite occurring in Spain and in Cornwall. W. Steinkuhler gave for Cornish torbernite the sp. gr. 3·68 at 17°, and the hardness 2; while for a specimen from Katanga he gave the sp. gr. 3·84 to 3·951 at 17°. The mean index of refraction of the Cornish specimen was 1·594 to 1·600, and for the Katanga specimen, 1·600 to 1·618. B. Stoces found for some Bohemian torbernites μ ranging from 1·610 to 1·628. According to A. F. Hallimond, the torbernite from Gunnislake, Cornwall, is metatorbernite, differing from torbernite in having the axial ratio $a : c = 1 : 2.97$, sp. gr. 3·22, and refractive indices $\omega = 1.592$, and $\epsilon = 1.582$. The sp. gr. of metatorbernite is 3·683 to 3·700; the refractive indices $\omega = 1.623$ and $\epsilon = 1.625$; and the axial ratio $a : c = 1 : 2.28$. A. H. Church said that the octohydrated mineral loses no water in dry air or in vacuo; but at 100° it loses 6 mols., and the remainder at a red-heat; Y. Bucholz said that the dodecahydrate loses 4 mols. of water in a desiccator; at 95°, it loses another mol.; at 148° to 156°, it loses another 4 mols.; at 220°, another 2 mols. are given off; and the last mol. is

expelled at a red-heat. According to F. Rinne, the tetragonal, negative, doubly refracting mineral loses some water at 60° to 65°, passing into a tetragonal *meta-torbernite* with a positive and feeble double refraction; and by the loss of more water at 100°, it passes into a series of rhombic meta-forms which resemble very closely autunite or lime-uranite. A. G. Bergman measured the vap. press. of the crystalline hydrate, and obtained the curves shown in Fig. 24, for $Ca(UO_2)(PO_4)_2.8H_2O$, $Cu(UO_2)_2(PO_4)_2.8H_2O$, and $Co(UO_2)_2(PO_4)_2.8H_2O$. E. Jannettaz found the ratio of the heat conductivities, a/γ, to be 1·5. F. Rinne found that the absorption spectrum between 510 and 440$\mu\mu$ shows five bands which are also characteristic of autunite. T. W. Case observed no evidence of photo-electric conductivity. H. Debray said that the mineral is not altered by heating it with water up to 200°; and when melted with sodium carbonate it forms copper uranite. H. von Foullon studied the products formed during the weathering of pitchblende. The *octohydrate*, the first product of the dehydration of the dodeca-hydrate, torbernite, was called by F. Rinne, and A. F. Hallimond **metatorbernite-I**, and the second product metatorbernite-II. When torbernite loses water, either in a desiccator or when heated, it changes to metatorbernite, acquir-ing another crystalline form and other optical properties. When torbernite is kept over sulphuric acid of different concentrations and at various temp., the points fall on one or other side of the transition curve of torbernite.

FIG. 23.—Transition Curve of Torbernite.

FIG. 24.—Vapour Pressures of Calcium and Cobalt Uranyl Phosphates.

When torbernite of sp. gr. 3·219 is heated under water for several hours at 100°, the sp. gr. changes to 3·67, and the loss in weight corresponds with the transition from the dodecahydrate to the octohydrate, Fig. 23. A morphotropic relation exists between the crystals of the two substances, and the extra 4 mols. of water are held in layers that alternate with basal layers having the constitution of metatorbernite. The mol. vol. of the extra water corresponds with a sp. gr. of 1·2. A. F. Hallimond thus contrasted the properties of torbernite and of metatorbernite :

	$a : c$	Sp. gr.	ω	ϵ
Torbernite	1 : 2·97	3·22	1·592	1·582
Metatorbernite { artificial .	—	3·67	—	—
{ natural . .	1 : 2·28	3·68	1·623	1·625

The mineral **autunite** is a variety of uranium-mica, or chalcolite, and J. J. Berzelius showed that it is *le sel à base de chaux, où l'oxide d'urane joue le rôle d'acide.* Accordingly, it has been called *lime-uranite,* and by A. Breithaupt, *calcouranite.* W. H. Miller called it autunite from its occurrence at St. Symporien, near Autun. It also occurs near Limoges, and Aubert, Puy-de-Dôme ; at Siebengebirge, Johanngeorgenstadt, Eibenstock, Steinbruch, Fuchsbau, and Falkenstein ; Lurisia, Italy ; Beira Alta, Portugal ; near Lake Omega, Russia ; near South Basset, Wheal Edwards, and St. Day, Cornwall ; Maharitza, Madagascar ; Tongking, China ; at Middletown, and Branchville, Connecticut ; Chesterfield, Massachusetts ; Acworth, New Haven ; Schnylkill, near Philadelphia ; in Mitchell Co. and Alexander Co., North Carolina ; Black Hills, South Dakota ; at Silver Reef, Utah ; etc. Analyses by C. Winkler, G. Lincio, F. Henrich, A. H. Church, A. Pereira-Forjaz, A. F. Hallimond, A. Laugier, J. J. Berzelius, F. Pisani, E. M. Péligot, E. Jannetaz, E. Boutée, and A. Lacroix are in agreement with **calcium uranyl phosphate,** $Ca(UO_2)_2(PO_4)_2.8H_2O$. Some varieties have 10 or 12 mols. of water. The colour of the mineral is lemon-yellow or sulphur-yellow. The mineral occurs in foliated aggregates with a micaceous structure, and in thin tabular crystals nearly

tetragonal in form, and with angles deviating but slightly from those of torbernite. A. des Cloizeaux gave for the axial ratios of the rhombic crystals $a : b : c$ $=0.9875 : 1 : 2.8517$. The (001)-cleavage is complete and basal; the laminæ are brittle. A. Brezina considered autunite from Johanngeorgenstadt to be monoclinic, with the axial ratios $a : b : c = 0.3463 : 1 : 0.3525$, and $\beta = 90° 30'$. The crystals were examined by W. Phillips, and G. Lincio. According to A. des Cloizeaux, the optical character is negative. The optic axial angle $2E$ is 60° 57′ at 17°; 57° 32′ at 47°; 56° 36′ at 71.5°; 55° 8′ at 81°; and 54° 10′ at 91°. F. Rinne also found that $2E$ falls with a rise of temp., and this much more rapidly than is indicated by the data of A. des Cloizeaux; indeed, F. Rinne found that $2E$ is zero at 75°. Even at 50° the polarization colours begin to shade off, and at 75° the crystal is isotropic; above 75° the mineral begins to lose water and passes into a new, probably rhombic, form—*meta-autunite*—which is stable up to 300°. The pleochroism is feeble; the optical character is negative. The sp. gr. is 3.05 to 3.19, and the hardness is 2.0 to 2.5. A. G. Bergman measured the vap. press. of the crystalline hydrate, and the results are illustrated by Fig. 24. A. des Cloizeaux found that the mean index of refraction is $\beta = 1.572$. A. Michel-Lévy and A. Lacroix gave for the indices of refraction $\alpha = 1.577$, $\beta = 1.575$, and $\gamma = 1.553$. F. Rinne observed that the absorption spectrum between 510 and 440$\mu\mu$ shows five distinct bands. F. Kohlbeck and P. Uhlich, E. Gleditsch, W. Marckwald and A. S. Russell, A. Muguet and J. Seroin, G. Lincio, etc., examined the radioactive properties of the mineral.

W. T. Schaller was able to replace sodium, potassium, barium, manganese, and lead for calcium in artificial autunite. J. G. Fairchild obtained artificial autunite by allowing soln. of uranium and calcium nitrates to mix slowly with phosphoric acid by diffusion through a large vol. of water. The first precipitate is amorphous, but large plates of artificial autunite were obtained when the system is left undisturbed for a month. If the soln. be treated with sodium chloride, calcium uranyl phosphate is no longer obtained, but a sodium autunite is precipitated. The same result is obtained by mixing soln. of calcium chloride and phosphoric acid in the proportions required for dicalcium phosphate, and adding this to a nearly boiling soln. of sodium chloride (150 grms. per 500 c.c.). This was mixed with 3.7 grms. of uranyl nitrate dissolved in a little water, so that the proportions were those needed to form $CaO.2UO_3.P_2O_5.8H_2O$. A small excess of the uranium salt does no harm. As the hot soln. slowly cools to the temp. of the room, yellow, 8-sided plates separate out. The degree of acidity of the soln. controls the size of the crystals. The analysis—P_2O_5, 16.13; UO_3, 64.90; CaO, 1.10; Na_2O, 5.62; and H_2O, 13.22—corresponds with sodium autunite; and the crystals have the indices of refraction $\omega = 1.605$ and ϵ is nearly the same. If this product be digested in a soln. of calcium chloride, of sp. gr. 1.25, 4- and 8-sided plates of **calcium autunite,** $CaO.2UO_3.P_2O_5.nH_2O$, are formed. The indices of refraction are $\omega = 1.600$ and $\epsilon = 1.590$. When calcium autunite is digested in a half sat. soln. of sodium chloride on the steam bath for 2 days, **sodium autunite** is formed in uniaxial plates with $\omega = 1.583$ and $\epsilon = 1.566$. If the sodium autunite is digested with a conc. soln. of potassium chloride, **potassium autunite** is formed in 8-sided plates with $\omega = 1.575$ and $\epsilon = 1.553$; with a soln. of barium chloride, **barium autunite** is formed, analogous with uranocircite, in uniaxial plates, with polysynthetic twinning, and having $\omega = 1.613$ and $\epsilon = 1.604$. A soln. of manganese chloride furnished **manganese autunite** in lamellæ with diagonal twinning, and having $\omega = 1.60$; copper chloride similarly furnishes **copper autunite,** with $\omega = 1.608$; nickel chloride gives greenish-yellow **nickel autunite;** cobalt chloride gives pinkish-brown **cobalt autunite;** magnesium chloride gives **magnesium autunite** in plates with $\omega = 1.48$; lead chloride gives a non-homogeneous product, but **lead autunite** is formed when the mixed nitrates of uranyl, calcium, and lead are allowed to react slowly with a $0.01M$-soln. of phosphoric acid through a vol. of 4 litres of water. The birefringent plates have $\omega = 1.625$.

A. F. Hallimond called a related yellow mineral from Basset, Cornwall, **bassetite.** It was analyzed by A. H. Church. The monoclinic mineral has the axial ratios $a : b : c = 0.3473 : 1 : 0.3456$, and $\beta = 89° \ 17'$; the (001)- and (100)-cleavages are good; the sp. gr. is 3·10; the optical character is negative; the optic axial angle $2E = 110°$; the indices of refraction are $\beta = 1.574$, and $\gamma = 1.580$; and the pleochroism, β, is deep yellow, and γ, pale yellow. Another related mineral from Gedruth, Cornwall, was called **uranospathite**; it is pseudotetragonal and rhombic, with $a : b : c = 1 : 1 : \longrightarrow$. It occurs in yellow or pale green tabular crystals, with $2V = 69°$; the cleavages (001) and (100) are good; the sp. gr. is 2·50; the indices of refraction, $\beta = 1.510$, and $\gamma = 1.521$; and the pleochroism, α, is pale yellow, and $\beta = \gamma$ is deep yellow.

C. Blinkoff prepared **calcium uranyl hydrophosphate,** $Ca(UO_2)(HPO_4)_2.nH_2O$, by heating uranyl nitrate with an excess of conc., aq. soln. of calcium hydrophosphate; at 50° to 60°, crystals of the *tetrahydrate* are formed; at 100°, the *trihydrate*; and at 250°, in a sealed tube, the *dihydrate*. According to C. Blinkoff, calcium uranyl phosphate is not produced by H. Lienau's method employed for the ammonium salt; nor is it obtained by mixing soln. of uranyl acetate and calcium acetate, or from an acetic acid soln. of calcium uranate and phosphoric acid. If, however, a nitric acid soln. of calcium phosphate mixed with an aq. soln. of uranyl nitrate, in the proportions $CaO : UO_3 = 1 : 2$, be heated in a sealed tube at 200° for a couple of days, yellow tetragonal plates of a basic salt, **calcium uranyl dioxytetraphosphate,** $3CaO.5UO_3.2P_2O_5.16H_2O$, or $Ca_3(UO_2)_5O_2(PO_4)_4.16H_2O$, are formed. C. Blinkoff added the calculated quantity $(UO_2 : PO_4 = 1 : 1)$ of phosphoric acid to a soln. of strontium uranate in acetic acid containing a few drops of nitric acid, and obtained a basic salt, **strontium uranyl oxytetraphosphate,** $2SrO.5UO_3.2P_2O_5.24H_2O$, or $Sr_2(UO_2)_5O(PO_4)_4.24H_2O$. If no nitric acid be used, and the soln. be much diluted before the addition of phosphoric acid, **strontium uranyl dihydrotetraphosphate,** $SrO.4UO_3.2P_2O_5.21H_2O$, or $Sr(UO_2)_4H_2(PO_4)_4.20H_2O$, is formed. A. Weisbach obtained yellowish-green crystals of a mineral resembling autunite from Falkenstein in Saxon Voigtland. He called it **uranocircite.** The analysis corresponds with **barium uranyl phosphate,** $Ba(UO_2)_2(PO_4)_2.8H_2O$, so that it is a *baryta-uranite,* or a *baryta-autunite.* The rhombic crystals have the (001)-cleavage perfect, and the (100)- and (010)-cleavages are distinct. The optic axial angle $2E = 15°$ to 20°. The sp. gr. is 3·53. According to A. H. Church, the mineral loses $6H_2O$ in vacuo over sulphuric acid, and the remaining $2H_2O$ is lost at a red-heat. P. Gaubert found that at 150° the mineral passes into a *meta-uranocircite,* analogous to meta-autunite. While uranocircite represents the octohydrate, C. Blinkoff prepared the *decahydrate,* $Ba(UO_2)_2(PO_4)_2.10H_2O$, in yellow plates, by adding phosphoric acid to a very dil. soln. of barium uranate in acetic acid; and the *tridecahydrate,* $Ba(UO_2)_2(PO_4)_2.13H_2O$, by adding the calculated quantity of phosphoric acid to a soln. of barium uranate in acetic acid to which a few drops of nitric acid had been added.

As previously indicated, the mineral phosphouranylite contains 4·4 per cent. of lead oxide. A. Schoep reported a radioactive mineral from Kasola, Katanga, Belgian Congo, as a canary-yellow powder, which under the microscope is seen to consist of rectangular scales—probably tetragonal. The mineral was named **dewindtite**—after J. Dewindt. The analysis, after deducting impurities, corresponds with **lead diuranyl phosphate,** $4PbO.8UO_3.3P_2O_5.12H_2O$, or possibly $Pb(UO_2)_2(PO_4)_2.3H_2O$. Its sp. gr. is 4·08, and the index of refraction exceeds 1·74. V. Billiet gave for the indices of refraction $\alpha = 1.762$ and $\beta = 1.763$. A. Schoep also found in the same locality a golden-yellow radioactive mineral which he named **stasite**—after J. S. Stas. It has the same composition as dewindtite, but consists of minute prisms with square terminations, and an index of refraction over 1·74. The cleavage is perfect in one direction, and the sp. gr. is 5·03. The evidence for the dimorphism of these minerals is doubtful. Another radioactive mineral from the same locality was called **parsonite**—after A. L. Parsons. Its analysis,

after deducting presumed impurities, corresponds with **lead uranyl phosphate,** $Pb_2(UO_2)(PO_4)_2.H_2O$. The colour is pale brown; the structure is earthy— minutely crystalline to compact; the tabular crystals are monoclinic or triclinic; the sp. gr. is 6·23. V. Billiet gave 1·85 for the α index of refraction of the mono- clinic crystals. A. Schoep obtained a similar radioactive mineral from Chinkolobwe, Belgian Congo. It was named **dumontite**—after A. Dumont. It forms trans- parent, ochre-yellow, biaxial, elongated prisms—probably rhombic—with the index of refraction over 1·78. It is strongly pleochroic—α, pale yellow; β, deep yellow. The analysis agrees with $2PbO.3UO_3.P_2O_5.5H_2O$. All the water is expelled at about 300°, and oxygen is lost at 500°. V. Billiet gave $\alpha=1·88$ and $\gamma=1·89$ for the indices of refraction of the rhombic crystals. A. Schoep also described **renardite**—named after A. F. Renard—from the Kasola mine, Katanga. Its composition corresponds with $PbO.4UO_3.P_2O_5.9H_2O$. It occurs in minute, yellow, flat, rectangular prisms belonging to the rhombic system, with $a:c=1:0·8327$; the (100)-cleavage is perfect; the indices of refraction $\alpha=1·715$, $\beta=1·736$, and $\gamma=1·73$; and the sp. gr. is just over 4. The pleochroism α is colourless and β and γ are yellow. The mineral fuses on charcoal to a black scoriaceous mass; and it is readily soluble in hot nitric or hydrochloric acid. In the latter case, lead chloride is deposited as the soln. cools.

A. Breithaupt described a mineral observed on the uranium minerals of Autun, France; Steinig, Saxon Voigtland; Neuhammer, Bohemia; and Johanngeorgen- stadt, Saxony. The mineral resembles autunite in the four-sided rhombic plates, nearly tetragonal. Its colour is reddish-brown or hyacinth-red, and it is con- sidered to be **manganese uranyl phosphate,** or mangano-uranite. It was called **fritzscheite**—after C. L. Fritzsche. The sp. gr. is 3·504, and the hardness 2·0 to 2·5.

P. Pascal prepared **silver, barium, and lead uranylhexametaphosphates,** $M_4[UO_2(PO_3)_6]$. They are obtained by fusing the alkali trimetaphosphate at about 700°, and chilling the fused mass rapidly. The product forms the complexes indicated when treated with salts of the corresponding metals.

A. W. Cronander prepared *uranium phosphodecachloride,* $UCl_5.PCl_5$—*vide supra.* A. Colani treated metaphosphoric acid with uranium tetrachloride at a dull red- heat, and obtained **uranous tetrachlorophosphate,** $U_3(PO_4)_4.UCl_4$; and also by the action of uranium tetrachloride on uranous pyrophosphate. The green rhombic crystals have the axial ratios $a:b:c=0·8376:1:0·3737$. Twinning occurs about the (101)-plane; and the (101)- and (100)-cleavages are complete. The salt is sparingly soluble in hydrochloric acid, but readily soluble in nitric acid, and aqua regia. J. Aloy obtained **uranous tetrachlorohydrophosphate,** $U(HPO_4)_2.UCl_4$, in green crystals, from a soln. of uranous hydrophosphate in conc. hydrochloric acid.

W. Heintz allowed a mixture of nitric acid and uranyl hydrophosphate to stand in the cold, and obtained aggregates of yellow microscopic prisms of **uranyl nitratophosphate,** $2UO_3.N_2O_5.P_2O_5.16H_2O$. The salt melts when heated, and gives off nitrous fumes and water. It is soluble in warm water, and the soln. deposits the hydrophosphate $(UO_2)(HPO_4).4\frac{1}{2}H_2O$. The salt is soluble in nitric, hydro- chloric, and sulphuric acids; acetic acid does not form a clear soln. in the cold.

CHAPTER LXIV

MANGANESE

§ 1. The History of Manganese

THE mineral commonly called *pyrolusite* has been known from ancient times. It was used then, as it is now, for bleaching glass; this it does by disguising in some way the green or yellow colour produced by iron oxides present as impurities in the raw materials, etc. Indeed, it is the references to the use of this mineral for decolorizing glass which enable the specific mineral to be traced through writings from the first century up to the present time. In the first century of our era, Dioscorides, in his Περὶ ὕλης Ἰατρικῆς (5. 93), referred to the μάγνης λίθος as a mineral which had the power of attracting iron; and Pliny, in his *Historiæ naturalis* (**36**. 25, 66), to the *magnes* or *lapis magnes*—that is, the loadstone, or magnetic oxide of iron. Pliny said :

> What is there endowed with more marvellous properties than the *magnes* ? In which of her departments has Nature displayed greater waywardness ? What is there in existence more inert than a piece of rigid stone ? And yet, behold ! Nature has endowed the stone with both sense and hands. What is there more stubborn than iron ? Yet the iron allows itself to be attracted under the mysterious and invisible influence of the *magnes*, for the iron springs towards it, and is held fast by its embraces.

Pliny then described five different kinds of *lapis magnes*, and he classed them as male and female. The male varieties were said to be more red than black; and he added that the fourth kind, found near Alexandria, in Troas, is black, of the female sex, and consequently has no attractive power; while the fifth kind comes from Magnesia, in Asia, is white, and has no attractive power. Pliny here seems to get confused in his classification. Pliny also said that in Ethiopia there is *hæmatites magnes*, a mineral of blood-red colour. The *hæmatites* has not the same property of attracting iron as *lapis magnes*. In the second century of our era, C. Galen [1] described bloodstone as *magnites*. In describing the manufacture of glass, Pliny said that " in the course of time, as human industry is ingenious in discovering, *lapis magnes* began to be employed as one of the ingredients of glass, from the impression that a magnet could attract glass as well as iron." Whether or not *lapis magnes* was first used in glass-making from the application of a wrong hypothesis, it is more probable, said J. Beckmann, that the early glass-makers tried various minerals for colouring glass; and they must have soon found that one kind of *lapis magnes*, according as it is used in greater or less quantity, imparts to glass many beautiful shades of colour—violet, red, and dark brown. They probably also found that when a very small proportion of this kind of *lapis magnes* was added, the glass became colourless. In this way the glass-makers were able to make glass vessels which, in the words of Pliny, were " entirely colourless and transparent, and as nearly as possible resembled rock crystals "—*Maximus tamen honos in candido translucentibus, quam proxima crystalli similitudine*. The evidence is thus fairly clear that some varieties of pyrolusite, on account of their external resemblance to the magnetic minerals, were classed with the *lapis magnes*. Pliny added that, on the authority of Nicander, the term *magnes* comes from the name

of the person who was the first to discover the mineral on Ida, for when Magnes was taking his herds to pasture he found that the nails of his shoes and the iron ferrule of his staff adhered to the ground. Pliny said that the *lapis magnes* was also called *sidera*, as well as *heraclion*. The former term no doubt comes from the Greek σίδηρος, iron, and the latter from Heraclea in Lydia or Thessaly. The term *magnesia* can also be referred to the locality, Magnesia, where the fifth variety of *lapis magnes* occurred. According to L. Delâtre, the term is derived from μάγγανον, meaning a delusion or mystification, in allusion to the brittle and unstable (oxidizable) nature of the metal which it furnished. Writers in the Middle Ages came to use the term *lapis magnes* or *lapis magnesius* for the magnetic variety, and *magnesia* for the non-magnetic mineral of a similar appearance. Thus, the tenth-century Arabian writer Avicenna, in his *Canon medicinæ* (Venetiis, **1**. 356, 1608), has a chapter entitled *De magnete*, and another entitled *De magnesia*, and he definitely distinguishes between the magnetic and the non-magnetic minerals; while the thirteenth-century Albertus Magnus, in his *De mineralibus*, said that *magnesia*, which some call *magnosiam*, is a black mineral frequently used in glass-making. The use of the mineral in glass-making was mentioned by Roger Bacon, Basilius Valentinus, C. Leonardus, B. P. de Vargas, R. Boyle, M. Mercatus, A. Neri, and many others. V. Biringuccio said that the mineral *manganese* which is found at the mountain of Viterbo, Tuscany, as well as in Germany, is the colour of iron-slag. He added that no metal can be obtained from it by fusion, but it imparts a fine azure colour to glass; and when put into molten glass, the glass is cleansed, even if it were green or yellow. In a hot fire it gives off a vapour like lead, and turns into ashes. G. Agricola made similar remarks about the use of *magnes* in glass.

About this time the word came to be written in many ways—H. Cardanus, and M. Mercatus used *manganensis*, C. Leonardus, *manganesum*, and V. Biringuccio, *manganese*. In addition, D. G. F. C. Fuchs said that the terms *manganesia*, *magnesie*, *mégalaise*, *magalaise*, *magne*, *magnesia vitriariorum*, *magnesium*, *magalœa sitiens*, and *ferrum nigricans spledens Wolstersdorfi* were employed. O. Vogel discussed the origin of the term "manganese."

Paracelsus spoke of the *magnesia* of the philosophers, but did not refer to its use in glass-making—*vide* **4**. 29, 1. As indicated in connection with magnesium, the term *magnesia alba* was applied to the magnesian earth in contrast with *magnesia nigra* applied to the mineral now under discussion. The term *Braunstein* appears in Basilius Valentinus' *Letztes Testament*, where the word is used for the ferruginous earths employed by potters for painting; C. Schwenkfeld used the word in a similar connection. A. Cæsalpinus referred to *lapis manganensis* as *ferrum mineralisatum*, *minera fuliginea, manus inquinante, quæ sparsim striis conuergentibus constat*; and nearly a century later the Swedish mineralogist J. G. Wallerius included with *brunsten* the varieties *magnesia solida, magnesia striata, magnesia squamosa*, and *magnesia tessulate*, used in tempering the colour of glass. S. A. Forsius called the mineral *manganaise gris*, and C. von Linnæus, *molybdenum magnesii*. W. Haidinger called the different varieties of these earths **pyrolusite**—from πῦρ, fire; λούειν, to wash, in allusion to their use for discharging the yellow and green colour from glass, and they were whimsically called *sapo vitriariorum*, or *le savon des verriers*, by J. B. L. Romé de l'Isle.

The mineralogists of the eighteenth century did not make much progress in establishing *Braunstein* as a specific mineral, for this term, as well as the several variants of *lapis magnes*, was applied to common iron ores, and sometimes to pyrites. Observations on the mineral were made by J. C. V. de Bomare,[2] F. E. Brückmann, F. A. Cartheuser, G. de Courtivron, J. A. Cramer, C. E. Gellert, E. F. Geoffroy, C. A. Gerhard, J. F. Henkel, B. C. J. von Hermann, J. Hill, P. J. Hjelm, J. C. Ilsemann, J. H. G. von Justi, V. Kräutermann, J. G. Lehmann, H. Maret, L. B. G. de Morveau, J. T. A. Peithner, M. Pomet, J. B. L. Romé de l'Isle, M. B. Valentini, J. G. Wallerius, J. F. Westrumb, J. L. Woltersdorf, and

J. J. Woyt. A. Libavius erred in classifying the mineral with the antimony ores; and C. von Linnæus, with molybdenum ores. J. H. Pott showed that the iron contained in the mineral is an accidental and not an essential constituent, and he obtained a number of salts from the mineral, but he did not recognize that he had in hand the salts of a new metal. In common with J. W. Baumer, S. Rinman, G. A. Scopoli, C. F. G. H. Westfield, A. G. Werner, G. de Courtivron, and C. A. Gerhard, J. H. Pott regarded *Braunstein* as one of the alumina earths. A. Cronstedt supposed that the mineral contained essentially tin; and B. G. Sage inferred that it is a mineralized mixture of cobalt and zinc. In 1770, J. G. Kaim extracted a regulus by heating a mixture of pyrolusite and black flux at a high temp., but this observation does not appear to have been followed up.

In 1774, C. W. Scheele,[3] in his memoir: *Om Brunsten eller Magnesia*, showed that *Braunstein* is the oxide of a peculiar metal, for in its reactions with acids and various other reagents it gives results exhibited by the oxide of no other metal. He said that *Braunstein* contains a calx which resembles lime in many respects, and he even tried to find if the one can be converted into the other, but with negative results. He showed that the mineral has a strong attraction for phlogiston—meaning that it readily gives off oxygen—and forms colourless salts. Soln. of manganese which did not contain phlogiston—meaning the oxidized salts—were coloured. As a result of his experiments to discover the constituent parts of *Braunstein*, C. W. Scheele said: " I have not yet been able to produce the metal or confirm by synthesis what I have learnt by analysis." T. Bergman pointed out that although the new metal had not been isolated, its existence had been *incontestablement établie* by C. W. Scheele. J. G. Gahn isolated the metal in 1774. A report of the investigation does not appear to have been published. C. W. Scheele must have been closely connected with the work, and he supplied J. G. Gahn with materials. This is shown by the following excerpt from a letter from C. W. Scheele to J. G. Gahn:

<div align="right">Upsala, den 16 Mai 1774.</div>

Hochgeehrter Herr !

I am sending herewith some *depurirten Braunstein*, in which, I think, it will be difficult to detect any iron. I should have sent it by the previous post, but I had none ready. I have tested your *reducirten Braunstein*, and find that it is a *Braunsteinerde* united with a little iron and much phlogiston. Your experiment therefore gives me great satisfaction, and I am eager to know what will be the result of treating this purified pyrolusite in your furnace. I trust that you will send me a little of the regulus as soon as possible.

<div align="center">Ich bin Dero dienstschuldigster Diener,
C. W. SCHEELE.</div>

The " reduced pyrolusite," " regulus," and the " pyrolusitic ore united with a little iron and much phlogiston " obviously refer to J. G. Gahn's isolation of the manganese. Immediately afterwards T. Bergman obtained what he called *magnesium*, or *magnesium regulinum*. These observers do not appear to have known that J. G. Kaim, four years earlier, had obtained a regulus from *Braunstein*. In the English translation of T. Bergman's memoir, the metal is called *manganese*. There was some confusion about this time in the nomenclature. The metal was also called *Braunsteinkönig*, or *Braunstein regulus*, and *Braunstein metal*. M. H. Klaproth at first used the term *Braunsteinkalk*, and this appeared in the English translation as *oxide of manganese*; and soon afterwards (1807) M. H. Klaproth himself adopted *manganese* for the name of the element. The term *manganese* was advocated by P. K. Buttmann, and it quickly came into general use—*vide* magnesium, **4.** 29, 1. M. F. Brünnich, R. Kirwan, and C. G. Hagen at first regarded manganese as a semi-metal—*Halbmetall*. The observations of J. G. Gahn, and T. Bergman were subsequently confirmed by P. de la Peyrouse, L. B. G. de Morveau, H. T. Scheffer, R. Kirwan, S. Rinman, J. C. Ilsemann, F. A. C. Gren, P. J. Hjelm, J. J. Bindheim, and J. F. John. The development of our knowledge of the individual compounds is indicated in connection with the descriptions of them.

§ 2. The Occurrence of Manganese

Manganese itself does not occur native, but it is widely diffused in small quantities as oxide, silicate, and carbonate, and less frequently as sulphide, phosphate, tungstate, columbate, etc. Manganese is about the fifteenth in the list of the most abundant elements in the earth's crust. F. W. Clarke [1] estimated that the known igneous rocks of the earth's crust contain 0·125 per cent. of Mn; shales and sandstones contain traces; while the limestones of the earth's crust contain 0·05 per cent. MnO. The known terrestrial matter in the earth's lithosphere contains 0·09 per cent. of Mn; H. S. Washington gave 0·07 per cent. F. W. Clarke and H. S. Washington gave 0·10 per cent. Mn for the average composition of the known igneous rocks, whilst J. H. L. Vogt gave 0·075 per cent. Manganese is less abundant than titanium or hydrogen, and more abundant than sulphur, carbon, copper, and nickel. W. Vernadsky gave 0·028 for the percentage amount of manganese in the earth's crust, and 0·09 for the percentage atomic proportion of manganese. W. and J. Noddack and O. Berg gave 7×10^{-2} for the absolute abundance of manganese in the earth; and A. von Antropoff gave for the atomic percentages 0·36 in stellar atmospheres; 0·035 in the earth's crust; and 0·06 in the whole earth. The subject was discussed by H. S. Washington, O. Hahn, J. Joly, V. M. Goldschmidt, G. Tammann, E. Herlinger, P. Niggli, H. von Klüber, and R. A. Sonder.

Manganese also occurs in extra-terrestrial bodies. H. A. Rowland [2] included manganese in his list of elements whose presence had been established in the sun. Reports of spectroscopic observations on the manganese lines in the solar and stellar spectra were made by J. N. Lockyer, S. A. Mitchell, S. Albrecht, P. W. Merrill and C. G. Burwell, C. Young, C. G. Abbot, F. J. M. Stratton, H. von Klüber, H. N. Russell, C. H. Payne, E. P. Waterman, P. W. Merrill, J. Stebbins, W. C. Rufus, C. D. Shane, G. E. Hale and co-workers, F. McClean, A. J. Angström, and A. Cornu. W. W. Morgan studied the manganese lines of α-Andromedæ. In 1804, M. H. Klaproth [3] observed the occurrence of manganese in meteorites from Siena, Lissa, Smolenski, and Stannern, and since that time numerous analyses have been reported in which the manganese ranges up to 5·77 per cent., as F. Koch found to be the case with a meteorite from Mocs. G. Berg, and E. Herlinger reported an average of 0·22 per cent. in stoney meteorites; and O. C. Farrington, an average of 0·03 per cent. in all available analyses of meteorites. J. and W. Noddack's estimates of the percentage composition, and of the atomic distribution relative to oxygen unity, are:

Earth's crust.	Igneous rocks.	Meteoric iron.	Troilite.	Atomic distribution.
$8·0 \times 10^{-4}$	$2·05 \times 10^{-3}$	$3·0 \times 10^{-4}$	$4·6 \times 10^{-4}$	$1·6 \times 10^{-3}$

F. Zambonini found manganese occurring in mineral vesbine from Vesuvian lava. The manganese minerals occur in igneous, metamorphic, and sedimentary rocks. They also occur in mineral veins traversing these rocks, as original minerals formed at the same time as the enclosing rock, or as *secondary* minerals formed by the chemical alteration of pre-existing minerals in the rocks or veins or by the introduction from without of manganese salts in soln. Secondary manganese minerals are also formed by the weathering of these minerals when they are exposed at the surface. The oxides of manganese occur in metamorphic rocks and in veins, but rarely in igneous rocks—O. A. Derby [4] described such a case. The carbonates occur in all except the igneous rocks. The silicates are characteristic of metamorphic rocks; they also occur in igneous rocks, rarely in mineral veins, and seldom if ever in sedimentary rocks; the titanosilicates are found in igneous and metamorphic rocks; the columbates, tantalates, and tungstates are found in veins in igneous rocks; while the phosphates, arsenates, and antimonates occur in both

igneous veins and metamorphic rocks.   The formation of manganese deposits
has been discussed by R. Beck and W. H. Weed, J. Bellinger, G. Bertrand, G. Bischof,
F. W. Clarke, L. Demaret, C. F. Drake, W. H. Emmons, L. L. Fermor, E. Fuchs
and L. de Launay, G. de Geer, E. C. Harder, S. Iimori, C. A. Moreing, R. A. F. Pen-
rose, G. Rother, H. Lasch, A. W. Stelzner and A. Bergeat, G. A. Thiel, J. H. L. Vogt,
T. L. Watson, G. Berg, etc.

Manganese and iron are dissolved from crystalline rocks, going into soln. as
sulphate or carbonate, and being re-deposited as carbonate, oxide, or hydroxide ;
and E. C. Sullivan showed that the manganese is dissolved by carbonated water
or dil. sulphuric acid more readily than iron.   V. Vincent made some observations
on the solubility of different forms of manganese in carbonated water.   Manganese
dissolved as carbonate, sulphate, or phosphate is precipitated by oxidation generally
in the form of pyrolusite, as hydrated psilomelane, wad, or as hydrated hemi-
trioxide.   The colloidal or gel precipitate readily adsorbs barium, potassium, and
other salts ;   and as shown by A. Gorgeu, it may slowly crystallize.   This deposi-
tion is exemplified by the dendritic infiltrations which occur in many rocks, as
illustrated by Fig. 1 by L. L. Fermor, which shows the dendrites of manganese

Fig. 1.—Dendritic Infiltration of Manganese Oxide on Sandstone (Central India).

oxide on some sandstone in Central India ;   and by the black coating which may be
found covering river pebbles, or surrounding manganiferous springs.   H. Leitmeier
discussed dendritic formations.   W. A. Tarr discussed the rhythmic banding of
manganese dioxide in a tuff.   G. A. Thiel found that manganese is deposited from
very dil. soln. of manganese sulphate or hydrocarbonate (32 to 200 parts Mn per
million), with or without peat solution or ferrous sulphate, when kept in contact
for several months at the ordinary temp. with various minerals and rocks in a
powdered form.   Magnesium carbonate, either as a mineral or as a rock con-
stituent, is the most active agent for precipitating manganese from such solutions.
Iron carbonate and calcium carbonate produce partial precipitation from carbonate
solutions, but have no effect on sulphate soln. in association with humic acid.
Silicates are very inactive.   The nodules of manganese dioxide are found as nodular
concretions made up of concentric layers—thin on the outside but thicker in the
interior.   Many contain fragments of pumice-stone, sharks' teeth, mollusc shells,
coral, etc., as nuclei.   The deep-sea nodules were found by the Challenger expedition
in the deep-sea red-clay at depths of about 2220 fathoms, and they were especially
abundant between Hawaii and Japan.   The Gazelle expedition found the manganese
nodules in many parts of the Pacific Ocean, and particularly near Cook Island ;
while C. Chun found manganiferous iron nodules in the South Atlantic Ocean at
a depth of 6700 metres.   A. H. Church called the nodules *pelagite*, and they have

been also called *halobolite*. Similar nodules were found by N. Andrussoff in the Black Sea, and by J. Y. Buchanan in the shallow waters of Lock Fyne, Scotland, but, as shown by J. Murray, they are more characteristic of the deeper ocean abysses. Similar nodular forms of terrestrial origin were recorded by M. Thresh, and W. M. Doherty. J. Murray and R. Irvine suggested that the manganese nodules are derived from the subaqueous decomposition of volcanic debris ; but C. W. von Gümbel attributes their formation to submarine spring waters holding manganese in soln., which is precipitated by contact with sea-water. J. Y. Buchanan assumed that organic matter reduced the sulphates of sea-water to sulphides, which precipitated the iron and manganese as sulphides, which were subsequently oxidized, but R. Irvine and J. Gibson showed that sea-water would decompose the sulphide to form soluble manganese hydrocarbonate. J. B. J. D. Boussingault, and L. Dieulafait supposed that the manganese oxide is formed by the oxidation of the carbonate in soln. at the surface, and that the precipitated oxide subsides to the sea-bottom. The sedimentary deposits may be formed in many ways. Bog, swamp, and sinter deposits, as wad, are common, and have been described by F. R. Mallet, L. L. Fermor, G. Bischof, H. Lasch, and J. H. L. Vogt. As in the case of hydrated iron oxide (*q.v.*), bacteria play an important part in the deposition of hydrated manganese oxide. Pipes and meters serving manganiferous water acquire a thin layer of yellowish iron oxide on the walls, and over this is a layer of a mixture of manganese and iron oxides. The subject was discussed by C. Zapffe.

Curiously enough, although the manganese and iron are dissolved from the rocks by the same reagents, they may be partially separated when the re-deposition occurs. The separation is not complete, for nearly all limonites contain some manganese, and nearly all psilomelanes contain some iron. C. R. Fresenius found that the warm carbonate waters of Weisbaden deposit the iron as hydroxide, leaving the manganese in soln. as hydrocarbonate. The manganese is thus carried by the water further than the iron. E. C. Sullivan also found that almost all the iron is precipitated by calcium carbonate from a mixed soln. of ferrous and manganese sulphates before manganese is deposited. This is in agreement with the thermochemical argument of L. Dieulafait. F. P. Dunnington also proved that acidic soln. of ferrous sulphate formed by the oxidation of pyrites, etc., can dissolve manganese oxides, forming, under favourable conditions, ferric sulphate and hydroxide. The soln. of ferrous sulphate, in contact with manganese carbonate, is rapidly oxidized by air, forming manganese sulphate, ferric hydroxide, and carbon dioxide. When the mixed iron and manganese sulphates come in contact with limestone, the two iron sulphates react, forming carbon dioxide, ferric hydroxide, and calcium sulphate, while in the absence of air the manganese sulphate has very little action on calcium carbonate, although in the presence of air, manganese oxide is gradually formed. Consequently, when a soln. of the mixed sulphates percolates through limestone, the iron will be precipitated and the manganese will remain in soln. until the soln. in contact with calcium carbonate is exposed to air. G. A. F. Molengraaff made observations on the manganese nodules.

From the thermochemical relations : $2FeO+O=Fe_2O_3+26\cdot6$ Cals., and $2FeO+2CO_2=2FeCO_3+10\cdot0$ Cals.; and $2MnO+O_2=2MnO_2+21\cdot4$ Cals., and $2MnO+2CO_2=2MnCO_3+13\cdot6$ Cals., it is probable that when oxygen and carbon dioxide in excess are in contact with weathering silicate rocks, the oxides Fe_2O_3 and MnO_2 and not the carbonates will be formed ; while if the gases are not in excess, Fe_2O_3 and $MnCO_3$, not MnO_2 and $FeCO_3$, will be formed. Ferrous carbonate —spathic iron ore—will be formed under reducing conditions. Other things being equal, if minerals are formed from aq. soln., that which has the greatest heat of formation should preponderate over the others. Of the common manganese compounds :

	MnS	MnO	MnCO_3	MnO_2
(Heats of formation) .	22·6	47·4	54·2	58·1 Cals.

pyrolusite, MnO_2, might be expected to preponderate over the others. As a matter

of fact, this mineral is the most abundant ore of manganese, while manganese sulphide with its small heat of formation is comparatively rare. There is need for more care than usual in applying thermochemical data to geological problems, because minerals may be formed under very different conditions—temperature and pressure—from those which obtained when the data were determined.

The geographical distribution of manganese [5] is illustrated by the map, Fig. 2. The main localities are as follow :

Europe. The manganese ores of the **United Kingdom** [6] are derived mainly from deposits in Wales—Carnarvonshire and Merionethshire—where rhodochrosite predominates ; and from Launceston, Cornwall, and Brentor, Devon, where the chief ores are pyrolusite and rhodonite. A little wad is obtained in Derbyshire. The manganese ores in Scotland have been worked only on a small scale ; and in Ireland there are occurrences at Sutton, Co. Dublin, and a few other unimportant localities. The chief occurrences of manganese ore in **France** [7] are at the Cabesses mine, Dept. Ariège, and mines in the department of Saône-et-Loir. The former ceased work in 1904, and the output from the latter is small. The production of manganese ore in **Portugal** [8] is small. The workable deposits of manganese ore in **Spain** [9] are the carbonate in Seville, Ciudad Real, Huelva, Gerona, and Oviedo. In **Italy** [10] deposits of manganese ore occur in Liguria, Tuscany, etc.; on Monte Argentario ; Carrara ; Rapolano ; the Island of Elba ; Turin ; Pralorgnan ; Piedmont ; and

FIG. 2.—The Geographical Distribution of Manganese Ores.

Gambetesa. The ore is usually somewhat siliceous. There are also deposits in Sardinia, and at Iglesias, on San Pietro Island, off Sardinia. Deposits of manganese ore occur in **Greece** [11] on the islands of Milo and Andros, but the output is small. There are also the Kassandra mines of Salonika. In **Turkey** [12] there are deposits in Aidin, Pirga, and Surmenéh. Occurrences have been reported in **Yugoslavia** [13]; **Albania** [14]; near Brosteni, Sucéva, and at the Arschitya mine near Jakobeny, **Roumania** [15]; and Wandenlitzen in **Carinthia** [16]; in the old **Austria-Hungary**,[17] including Bosnia and Herzegovina, the chief producing centres are Bukovina and Carinthia. Deposits also occur in Carniola, Bohemia, Istria, and Styria. In **Bulgaria** [18] there are deposits at Jamboli, Bela, and Dobra Nadejda. Nearly all the manganese ore produced in **Germany** [19] comes from the neighbourhood of Coblentz ; and there are manganiferous iron ore deposits near Siegen and Nassau. In **Belgium** [20] manganiferous iron ore is mined in the province of Liège. In **Sweden** [21] the chief producing districts are Undenäs, West Gothland, Wermland, and Jönköpings. The ore obtained is pyrolusite and manganite, hausmannite and braunite, and carbonate and silicate accompanying iron ores. The bulk of the world's output is obtained from **Russia.**[22] The Georgian deposits are estimated by D. Zereteli to contain 220×10^6 tons, while 73×10^6 tons have already been extracted—principally from the Tschiaturi mine. There are also extensive deposits in the Union of Socialist Soviet Republics—notably in the Nikopol and Gaisinsk districts, the Urals, Siberia, and North Caucasia.

Asia. A. Gaudry [23] described the manganese deposits of **Cyprus.** In **Asia Minor** [24] there is a deposit of ore, chiefly psilomelane and manganite, near Surmeneh, on the Black Sea. A large proportion of the world's supply of manganese ore comes from **India.**[25] The deposits of economic value are thus divided by L. L. Fermor : (i) those associated with a

series of manganiferous intrusives, notably in Vizagapatam, Madras ; (ii) those associated with the Dharwar rocks, in Gangpur, Panch Mahals, Jhabua, Balaghat, Bhandra, Chindwara, and Nagpur ; and (iii) those occurring as lateroid replacements on the outcrops of the Dharwar rocks in Singhbhum, Jubbulpore, Bellary, Sandur, Chitaldrug, Kadur, Shimoga, and Tumkur, and in Goa of Portuguese India. There is a small deposit at Ampitiya in Ceylon.[26]

A. A. Sankoff [27] described the deposits in Kara-Tschaguir, **Fergana**. In **Borneo** [28] manganese occurs at Gunong Bessi and in Bandjermassin. Deposits occur in Pengasih and Nanggolau, **Java** ; there is a deposit of manganese ore in the **Federated Malay States**, at Tambun ; and in the **Philippines**,[29] in Nagpartion, and on the island of Masbate. The deposits in **China** [30] were described by V. K. Ting. There are numerous deposits of manganese ore in **Japan** [31]—in Hokkaido, Aomori, Kitayama, Akita, etc.

Africa. Large manganese deposits occur in **Morocco** [32] ; in **Tunis**,[33] near Ain-Mulares ; in **Algeria**,[34] at Soukahras and Tebessa ; and in the **Sinai** [35] peninsula—Um Bogma Hills, Gebel Um Rinna ; Wadi Kharig, Wadi Baba, Wadi Naseb, Wadi Abu Hamata, Bir Um Hand, Abu Zenima, Wadi Um Sakran, etc. In what was German **East Africa** manganese ore occurs in the Unaka district and in the Kipengele Hills. There is also a deposit in British East Africa ; in **Somaliland** [36] ; and in Portuguese **Angola**.[37] Manganese ores occur in the Katanga of the **Belgian Congo** [38] ; and on the **Gold Coast** [39] at Dagwina in the Wassaw district. A. E. Kitson described the deposits as of three types : (i) Manganese-bearing argillaceous phyllites and fine mica-schists, with subordinate siliceous phyllites. These rocks are only slightly altered, and the manganese oxide is in the form in which it was originally deposited in the sediments. (ii) Spessartite (manganese garnet)—quartz rock, with or without rhodonite (manganese silicate), associated with biotite-paragneiss, biotite-schist, amphibolite, etc. These are highly altered forms of the first group. (iii) Segregation deposits formed by surface concentration of manganese oxide during the weathering of rocks of the first and second types. The special economic importance of the manganese deposits is dependent upon the degree of concentration that has taken place. These deposits occur in numerous districts in the Gold Coast Colony, Ashanti, and the Northern Territories. Owing to folding of the sediments they are visible at many places from the Birrim River, near Dixcove, on the coast to the north-west corner of the Northern Territories, for a distance of some 440 miles. The largest deposit occurs at Insuta-Dagwin, Gold Coast. There are also deposits near Zuaragu, Wa, and Kalimbi Hill. A small deposit of lateritic manganese ore occurs near Somabula in **Rhodesia**,[40] and there is a deposit on **St. Helena**. According to R. Dent, an old pyrolusite mine occurs on Chowa, Kafulamadzi (the place of iron), east of Broken Hill ; and he suggested that the mines were worked in prehistoric times. In **South Africa** [41] there are deposits in the Cape Province—Hout's Bay, Constantia Nek, Kogel Bay, near Worcester, near Wellington, French Hoek, and Caledon. In the Transvaal there are deposits near Pretoria ; and in Natal, in the Vryheid district, Nyalisa, Bellevue, Kruisfontein, and Baviaan's Kranz.

North America. There are deposits of manganese ore in several provinces of **Canada** [42] —e.g. near Kaslo, British Columbia ; near New Ross, and at the Tenny Cape Mines, Hants Co., in Nova Scotia ; at Markhamville, Jordan Mountain, and Dawson Settlement in New Brunswick ; in the Nestapoca chain of islands, and on the Amherst Island in Quebec ; on Cypress Hill, Alberta ; and at Manuels, Topsail, Long Pond, Chepel Cove, and Briguo on Conception Bay, Newfoundland. In the **United States** [43] there are deposits in *California* in the Franciscan formation of the Coast Ranges, in the Sierra Nevadas, in the counties of Inyo, San Bernadino, San Joaquin, and Alameda. In *Virginia* there is a large deposit at Crimora, and in many other localities. In *Georgia* the commercially valuable deposits are limited to the northern part of the state. In *Arkansas* there are deposits in the Ouachita Mountains, and in the Batesville field in Independence and Izard counties. In *Montana* there are deposits of manganiferous iron ore in Western Butte and at Philipsburg. In *Idaho* there are deposits in Bannock Co. In *Colorado* there are deposits north-west of Leadville. In *Nevada* deposits occur in the Ely and Siegal districts of White Pine Co. In *Utah* there are several deposits near Monroe, Sevier Co. ; Manning Canyon, near Marysville ; near Junction, Piute Co. ; and near Pahreah, Kane Co. There are deposits at Tombstone in *Arizona* ; at Silver City, Kingston, and Lake Valley in New Mexico ; at Jewel Cave, *South Dakota* ; near Whitfield, in the Chilhowee Mountain Range, near Morristown, and near Sweetwater, *Tennessee* ; in Iron, Reynolds, and Madison counties in *Missouri* ; near Lehigh in *Oklahoma* ; in Cleburne, Cherokee, Blount, and Etowah counties in *Alabama* ; in the south-west of *North Carolina* ; in a belt extending from New Market, Greenwood Co., to McCormick, Abbeville Co. ; and in Chester and Greeneville counties, *South Carolina* ; Glenmore, *West Virginia* ; near Harper's Ferry, Keyser's Ridge, and Bear Creek, and in Montgomery and Frederick counties, *Maryland* ; South Wallingford, and the Brandon and Chittenden areas of *Vermont* ; at Ironton, and on the Broad Mountain and in the Philadelphia and Chester counties, in *Pennsylvania* ; near Clinton, *New Jersey* ; and manganiferous iron ore is mined in the Lake Superior iron district. In **Mexico** [44] manganese ore has been reported in the districts of Acatan and Tepexi, near Coxcatlan, Guerrero ; Sierrita de Tepeyahualco, Puebla ; at Pachua and Real del Monte, Hildalgo, and Tetela del Oro. In the **West Indies** [45] there are three groups of deposits in *Cuba* : the Christo, the

Ponupo, and the Cauto, north of Santiago ; and in the San Maestro range. There are deposits at Coteaux in *Hayti* ; at Marshall's Hall, Portland, in *Jamaica* ; and on *St. Thomas Island*.

In **Costa Rica** [46] there is a manganese ore mine at Playarreal. There are several deposits on the Atlantic coast of **Panama**.

South America. Fully 95 per cent. of the manganese ore produced in **Brazil** [47] comes from the Miguel-Burnier, Ouro Preto, and Lafayette districts of Minas Geraes. Manganese ore has also been found in the states of Bahia, Parana, Santa Catharina, and Matto Grosso. In **Chile** [48] there are ores in a limestone-chert formation in the Carrizal district ; ores embedded in sandstone, shale, and limestone in Las Canas, La Liga, Arrayan, and Corral Quemada ; and veins in volcanic flows in Acules and Los Chorros. Manganiferous iron ore occurs in **Uruguay**.[49] In **Argentine** [50] iron ores have been reported in San Luiz. In **Colombia** there are deposits on the Caribbean coast extending easterly for 30 miles from Puerto-Bello ; and at Madinga, Gulf of San Blas.

Australasia. In **Australia** [51] there are deposits in the Gladstone district of *Queensland*, also in the Rockhampton, Maryborough, Hodgkinson, Ipswich, and Darling Downs districts. Manganese ore has been reported in considerable quantities in different localities in *New South Wales*, chiefly in the Bathurst and Bendemeer districts ; in *Victoria*, at East Gippsland, and at Heathcote, Bendigo district ; in *South Australia*, Gordon and the Pernatly Lagoon ; there are unworked deposits at Zeehan, in *Tasmania*. Good quality manganese ore has been reported in many places in *West Australia*. In **New Zealand** [52] manganese ore has been found at Tikiora, Bay of Islands ; Parua Bay, near Whangarei ; Waiheke Island ; Pahiki Island, Hauraki Gulf ; the vicinity of Wellington ; Taieri Mouth, Otago ; etc.

Over a thousand well-defined minerals have been recognized in the earth's crust. Of these, nearly 150 contain manganese as an essential constituent, and many more contain smaller proportions. There are also many minerals which contain only traces of manganese, and these small proportions may have a remarkable effect on the colour of the mineral. W. N. Hartley and H. Ramage [53] discussed the occurrence of manganese in common minerals. Manganese, indeed, is one of nature's pigments. L. L. Fermor quotes the following examples :

As a very good example of this, *winchite* may be mentioned ; this is practically a variety of tremolite, a colourless mineral, but contains small quantities of manganese, iron, and alkalies, in addition to the usual constituents. The winchite, instead of being white or colourless, is blue or lavender in the hand-specimen, and shows very beautiful pleochroism, under the microscope, in shades of lilac and blue. In the same way *blandfordite* is a pyroxene containing a certain quantity of manganese and alkalies ; in the hand-specimen it is of a deep crimson colour, whilst under the microscope it shows a beautiful pleochroism, in shades of blue, carmine, and lilac, as has been noticed for any known mineral. Similarly the manganese-micas show various shades of pink, delicate green, orange, and lilac-brown, in thin scales examined under the microscope. As other examples of the effect on the colour of a mineral may be mentioned the manganese-epidote, *piedmontite*, and the manganese-sphene, *greenovite*.

The mineral oxides are usually different shades of black or grey ; the other manganese minerals may be coloured blue, pink, lilac, crimson, yellow, orange, green, and brown. The colours may be modified by other constituents, *e.g.* alkalies favour the violet and blue. L. L. Fermor said that a comparison of the composition and colour of similar minerals shows that red, pink, lavender, and allied tints are peculiar to manganese. In some Indian rose-quartzes the manganese can be extracted by boiling dil. sulphuric acid. M. Berthelot also attributed the colour of amethyst (*q.v.*) to manganese. The following is a list of the manganese minerals. It includes the oxides, manganates, sulphides, sulphates, chlorides, carbonates, silicates, titanosilicate, columbates, tantalates, phosphates, arsenates, antimonates, borates, and tungstates :

Agnolite, $H_2Mn_3(SiO_3)_4 + H_2O$. **Alabandite**, MnS, manganese monosulphide. **Allactite**, $Mn_3As_2O_8.4Mn(OH)_2$, manganese arsenate. **Allochroite**, manganiferous variety of andradite, $3CaO.Al_2O_3.3SiO_2$. **Altered mica**, *see* caswellite. **Alurgite**, a manganese-mica. **Ankerite**, $(Ca,Mg,Fe,Mn)CO_3$. **Anthochroite**, manganiferous diopside. **Apjohnite** (bosjemanite), $MnSO_4.Al_2(SO_4)_3 + 24H_2O$, manganese aluminium sulphate. **Aplome**, manganiferous variety of andradite, $3CaO.Al_2O_3.3SiO_2$. **Ardennite**, aluminium-manganese vanadiosilicate. **Arfvedsonite** (manganiferous), sodium-calcium, ferrous, iron metasilicate with manganese. **Arseniopleite**, calcium-manganese arsenate. **Arsenoklasite**, $(Mn_3(AsO_4)_2.2Mn(OH)_3$. **Asbolite**, wad with a large percentage of cobalt. **Asterolte**, variety of manganhedenbergite. **Astochite**, $(Mg,Mn,Ca)SiO_3$ and $(Na,K,H)_2SiO_3$.

Astrophyllite, $(Na,K)_4(Fe,Mn)_4Ti(SiO_4)_4$. **Atopite,** $Ca_2Sb_2O_7$ often with Mn. **Axinite,** $(Ca,Mn,Fe)_7Al_4B_2(SiO_4)_8$. **Babingtonite,** $(Ca,Fe,Mn)SiO_3$ with $Fe_2(SiO_3)_3$. **Bäckströmite,** $Mn(OH)_2$. **Barkevikite,** manganese-amphibole near glaucophane. **Barysilite,** $Pb_3Si_2O_7$ with Mn, Ca, and Mg. **Beldongrite,** $6Mn_3O_5.Fe_2O_3.8H_2O$. **Bementite,** $2MnSiO_2.H_2O$. **Berzeliite,** $(Ca,Mg,Mn)_3As_2O_8$. **Bixbyite,** $FeO.MnO_2$. **Blandfordite,** a manganiferous pyroxene. **Bog manganese,** manganese oxides with oxides of iron, barium, aluminium, silicon, and sometimes nickel and cobalt. **Bosjemanite,** *see* apjohnite. **Brackebushite,** $(Pb,Fe,Mn)_3V_2O_8.H_2O$? **Brandtite,** $Ca_2MnAs_2O_8+2H_2O$. **Braunite,** $3Mn_2O_3.MnSiO_3$. **Brostenite,** $2MnO_2.(Mn,Zn)O.2H_2O$. **Bushmanite,** $(Mn,Mg)Al_2(SO_4)_4+24H_2O$—*vide* apjohnite. **Bustamite,** $(Mn,Ca)SiO_3.nCaCO_3$, manganese-calcium metasilicate. **Calcimangite,** *see* manganocalcite. **Carpholite,** $H_4MnAl_2Si_2O_{10}$. **Caryinite,** $(Pb,Mn,Ca,Mg)_3As_2O_3$? **Caryopilite,** $4MnO.3SiO_2.3H_2O$. **Caswellite** (altered mica), Ca,Mg,Mn,Fe,Al silicate. **Cesarolite,** $PbO.3MnO_2.H_2O$. **Chalcophanite,** $(Mn.Zn)O.2MnO_2.2H_2O$, a decomposition product of franklinite. **Childrenite,** $(Fe,Mn)Al(OH)_2PO_4+2H_2O$. **Chloromanganokalite,** $4KCl.MnCl_2$. **Chondrarsenite,** $Mn_3As_2O_8.3Mn(OH)_2$, basic manganese arsenate. **Columbite-tantalite,** $(Fe,Mn)(Nb,Ta)_2O_6$, iron-manganese columbate and tantalate. **Corondite,** $R^{..}(Mn_2O_7)^{..}$, where R denotes Mn, Pb, etc. **Crednerite,** $3CuO.2Mn_2O_3$. **Danalite,** $(Be,Ge,Zn,Mn)_7Si_3O_{12}S$. **Dannemorite,** iron-manganese amphibole. **Dentrite,** a branching form of wad. **Dickinsonite,** chiefly (Mn,Fe,Na) hydrated phosphate. **Dietrichite,** $(Zn,Fe,Mn)Al_2(SO_4)_4+24H$. **Dysluite,** $(Zn,Fe,Mn)O.(Al,Fe)_2O_3$, zinc-manganese-iron graphite (spinel). **Edenite** (manganiferous), aluminous calcium-magnesium amphibole with manganese. **Eosphorite,** $(Mn,Fe)Al(OH)_2PO_4+2H_2O$. **Fairfieldite** (leucomanganite), $(Mn,Ca)_3(PO_4)_2.2H_2O$. **Fauserite,** $2MnSO_4.MgSO_4.15H_2O$, or $(Mn,Mg)SO_4.6H_2O$. **Ferrorhodonite,** $(Mn,Fe)SiO_3$, manganese-iron metasilicate. **Ferrostibian,** hydrated antimonate of Mn and Fe. **Fillowite,** $3R_3P_2O_8+H_2O$ with R=Mn, Fe, Ca, and Na_2. **Flinkite,** $MnAsO_4.2Mn(OH)_2$, manganese arsenate. **Fluorite** (manganiferous), CaF_2 with manganese. **Fowlerite,** $(Mn,Zn,Fe,Ca)SiO_3$, manganese-zinc metasilicate. **Franklinite,** $(Fe,Zn,Mn)O.(Fe,Mn)_2O_3$. **Friedelite,** $H_7(MnCl)Mn_4Si_4O_{18}$ (Groth); $H_7(MnCl)Mn_4(SiO_4)$ (Palache). **Gamsigradite,** manganese-hornblende. **Ganomalite,** $Pb_3Si_2O_7$. $(Ca,Mn)_3SiO_4$. **Ganophyllite,** $6H_2O.7MnO.Al_2O_3.8SiO_2$, manganiferous zeolite. **Graphtonite,** $(Fe,Mn,Ca)_3P_2O_8$. **Glauchroite,** $CaMnSiO_4$. **Greenovite,** a manganiferous sphene, $CaTiSiO_5$. **Grorollite,** a variety of bog manganese. **Gudmundite,** $FeSbS$. **Halobolite,** similar to pelagite, found in the deep sea. **Hancockite,** $H_2(Pb,Ca,Sr,Mn)_4(Al,Fe,Mn)_6Si_6O_{26}$. **Harstigite,** $H_7(Ca,Mn)_{12}Al_3Si_{10}O_{40}$. **Hauerite,** MnS_2, manganese disulphide. **Hausmannite,** Mn_3O_4, or $2MnO.MnO_2$. **Hellandite,** $Ca_2R^{...}_2(R^{..}O)_2(SiO_4)_3$ with $R^{..}$=Ce, Di, La, Al, Fe, Mn. **Helvite,** $(Be,Mn,Fe)_7Si_3O_{12}S$, or $3(Be,Mn,Fe)_2SiO_4.(Mn,Fe)S$. **Hemafibrite,** $Mn_5As_2O_8.3Mn(OH)_7+2H_2O$. **Hematolite,** $[(Al,Mn)AsO_4.4Mn(OH)_2$. **Hematostibiite,** $Mn_5Sb_2O_{13}$? **Hetaerolite,** $ZnO.Mn_2O_3.H_2O(?)$, a zinc-bearing hausmannite. **Hexagonite,** tremolite containing a little manganese. **Hielmite,** stanno-tantalate of V, Fe, Mn, and Ca. **Hollandite,** $m(Ba,Mn)_2MnO_5+nFe_4(MnO_5)_3$. **Hornblende** (manganiferous). **Hortonolite,** $(Fe,Mg,Mn)_2SiO_4$, manganiferous olivines. **Hübnerite,** near wolframite, but containing 20–25 per cent. MnO. **Hureaulite,** manganese phosphate. **Hydrorhodonite,** alteration product from rhodonite to serpentine. **Ilesite,** $(Mn,Zn,Fe)SO_4+4H_2O$. **Ilvaite** (manganiferous), calcium-iron silicate with manganese. **Inesite,** $2(Mn,Ca).SiO_3.H_2O$, manganiferous zeolite. **Jacobsite,** $(Mn,Mg)O.(Fe,Mn)_2O_3$. **Jeffersonite,** manganese-zinc pyroxene. **Juddite,** a manganiferous amphibole. **Kempite,** $MnCl_2.3MnO_2.2H_2O$. **Kaneite,** Mn_5As_4, manganese arsenide. **Kentrolite,** $2PbO.Mn_2O_3.2SiO$. **Keramohalite,** *see* apjohnite. **Knebelite,** $(Fe,Mn)_2SiO_4$. **Kutnohorite,** a ferruginous manganiferous dolomite. **Lampadite** (lepidophacite). **Lamprophyllite,** contains Na, Fe, Mn, Ti, and SiO_2. **Landesite,** $3Fe_2O_3.20MnO.8P_2O_5.27H_2O$. **Langbanite,** $m(Sb_2O_3)nFe_2O_3.Mn^{..}(Mn^{...},Si)O_3$. **Lavenite** $(Na_4,Ca_2,Mn_2,Zr)(SiZr)O_{32}$. **Lepidophacite,** *see* lampadite. **Leucomanganite,** *see* fairfieldite. **Leucophoenicite,** $H_2(Mn,Zn,Ca)_7Si_3O_{14}$. **Lithiophilite,** $Li(Mn,Fe)PO_4$, lithium-manganese-iron phosphate. **Loseyite,** a basic carbonate of zinc and manganese, $2(Zn,Mn)CO_3.5(Zn,Mn)(OH)_2$. **Luckite,** $(Fe,Mn)SO_4+4H_2O$. **Mallardite,** $MnSO_4.7H_2O$, manganese sulphate. **Manganandalusite,** manganiferous andalusite (Al_2SiO_5). **Manganapatite,** $[(Ca,Mn)F]Ca_4(PO_4)_3$, apatite with manganese replacing calcium to 10.5 per cent. MnO. **Manganbrucite,** brucite $(MgO.H_2O)$ with considerable manganese oxide. **Manganchlorite,** clinochlore $(H_8Mg_5Al_2Si_3O_{18})$ with 2.3 per cent. MnO. **Mangandiaspore,** a manganiferous diaspore. **Mangandolomite,** $(Ca,Mg,Mn)CO_3$. **Manganese-humite,** *see* leucophoenicite. **Mangan-grossularite,** $3(Ca.Mn)O.Al_2O_3.3SiO_2$. **Manganhedenbergite,** hedenbergite $(CaFe(SiO_3)_2)$, calcium-iron pyroxene, with 6.5 per cent. manganese. **Manganite,** $Mn_2O_3.H_2O$. **Manganocalcite** (calcimangite, spartaite), $(Ca,Mn)CO_3$, calcite $(CaCO_3)$ with varying amounts of manganese. **Manganocolumbite-manganotantalite,** $(Mn,Fe)(Nb,Ta)_2O_6$, manganese-iron columbate and tantalate. **Manganoferrite,** $(Fe,Mn)_3O_4$. **Manganolangbeinite,** $K_2Mn_2(SO_4)_3$. **Manganomagnetite** (manganmagnetite), magnetite (Fe_3O_4) with 4 to 6 per cent. manganese. **Manganophyllite,** biotite with considerable manganese. **Manganosiderite** (mangansiderite) $(Fe,Mn)CO_3$. **Manganosite,** MnO. **Manganostibiite,** basic manganese antimonate. **Manganopectolite,** pectolite $(HNaCa_2(SiO_3)_3)$ with 4 per cent. of MnO. **Mangan-vesuvianite,** silicate of Ca, Al, Fe, with Mn. **Marjatskite,** manganese-glauconite. **Masonite,** manganesian chloritoid. **Natrophilite,**

$NaMnPO_4$. Sodium-manganese phosphate. **Neotocite**, hydrated iron-manganese silicate. **Neptunite**, $R'_2R''TiSO_4O_{12}$, with $R'=Na,K$, and $R''=Fe,Mn$. **Oligonite**, *see* manganosiderite. **Ottrelite**, $H_2(Fe,Mn)Al_2Si_2O_9$. **Partschinite**, $(Mn,Fe)_3Al_2Si_3O_{12}$. **Pelagite**, $MnO_2.Fe_2O_3$ with SiO_2,Al_2O_3, and H_2O in mechanical admixture; found in the deep sea. **Peloconite**, *see* wackenrodite. **Piedmontite**, epidote $(HCa_2(Al,Fe)_3Si_3O_{13})$ with 5 to 15 per cent. Mn_2O_3. **Pinakiolite**, $3MgO.B_2O_3+MnO.Mn_2O_3$, manganese-magnesium borate. **Plumbomanganite**, $3MnS.PbS$. **Pollanite**, MnO_2, like pyrolusite chemically, but of different crystallographic form. **Polyadelphite**, *see* rothoffite. **Psilomelane**, $MnO_2(Mn,K_2,Ba)O$. nH_2O, or H_4MnO_5. **Purpurite**, $(Fe,Mn)_2O_3.P_2O_5.H_2O$. **Pyrochroite**, $Mn(OH)_2$, white manganese hydrate. **Pyrolusite**, MnO_2. **Pyrophanite**, $MnTiO_3$. manganese titanate. **Pyrosmalite**, $H_7[(Fe,Mn)Cl](Fe,Mn)_4Si_4O_{16}$. **Pyroxmangite**, $(Mn,Fe)SiO_3$. **Quenselite**. $2PbO.Mn_2O_3.H_2O$. **Rancierite** (or rancierite), $Mn_3O_4.2H_2O$. **Reddingite**, $(Mn,Fe)_3(PO_4)_2$, $3H_2O$. **Reissacherite**, a variety of bog manganese with a high percentage of water. **Retzian**, basic arsenate of yttrium earths, manganese, and calcium. **Rhodochrosite**, $MnCO_3$. **Rhodonite**, $MnSiO_3$, manganese metasilicate. **Richterite**, $(K_2,Na_2,Mg,Ca,Mn)_4$-$(SiO_3)_4$, sodium-magnesium-manganese amphibole. **Ræpperite**, zinc-bearing tephroite, manganiferous olivines. **Roscoelite**, vanadium mica sometimes with Mn. **Romanechite**, $(Ba,Mn)O.3MnO_2.H_2O$. **Rothoffite** (polyadelphite), manganese-calcium-iron garnet; manganiferous andradite $(Ca_3Fe_2(SiO_4)_3$; (polyadelphite $(Ca,Mn)_3.(Fe,Al)_2Si_2O_{12})$. **Salmite**, manganesian chloritoid. **Sarkinite**, $Mn(OH)_2.Mn_3As_2O_8$. **Scacchite**, $MnCl_2$. **Schefferite**, $6CaMgSi_2O_6.MgFeSi_2O_6.Mn_2Si_2O_6$, manganese pyroxene. **Seamanite**, $3MnO.(B_2O_5.P_2O_5)$. $3H_2O$. **Senaite**, $(Fe,Pb)O.2(Ti,Mn)O_2$. **Serandite**, a hydrated silicate of manganese associated with sodium, calcium, and potassium silicates. **Silfbergite**, *see* dannemorite. **Sitaparite**, $9Mn_2O_3.4Fe_2O_3.MnO_2.3CaO$. **Skemmatite**, $3MnO_2.Fe_2O_3.6H_2O$. **Soda-berzelite**, $(Ca,Mn,Na_2)_3As_2O_8$. **Spandite**, $3(Ca,Mn)O.(Al,Fe)_2O_3.3SiO_2$. **Spartaite**, *see* manganocalcite. **Spessartite**, $Mn_3Al_2(SiO_4)_3$, manganese-aluminium garnet. **Staurolite** (manganiferous), $H_2O.2FeO.5Al_2O_3.4SiO_2$ with manganese. **Stainierite**, $(Co,Fe,Al)_2O_3.H_2O$. **Stibiatil**, Sb_2O_5,Mn_2O_3 and FeO. **Strigovite**, $H_4(Fe,Mn)_2(Fe,Al)_2Si_2O_{11}$. **Sussexite**, $H(Mn,Zn,Mg)BO_3$. **Synadelphite**, $2(Al,Mn)AsO_4.5Mn(OH)_2$, manganese arsenate. **Szmikite**, $MnSO_4.H_2O$, manganese sulphate. **Tephroite**, Mn_2SiO_4, manganese olivine. **Triplite**, $R_3P_2O_8.RF_2$ with $R=Fe$ and Mn. **Triploidite**, $(Mn,Fe)P_2O_8.(Mn,Fe)(OH)_2$. **Trimerite**, $(Mn,Ca)_2SiO_4.Be_2SiO_4$. **Triphylite**, $Li(Fe,Mn)PO_4$, lithium-iron-manganese phosphate. **Troostite**, $(Zn,Mn)_2SiO_4$. **Urbanite**, $(Ca,Mg,Mn)SO_4+2NaFe''(SiO_3)_2$. **Varvicite**, an impure pyrolusite derived from the alteration of manganite. **Violan**, manganiferous diopside. **Vredenburgite**, $3Mn_3O_4$. $2Fe_2O_3$. **Wackenrodite** (peloconite), bog manganese with a considerable percentage of lead. **Wad**, impure mixture of manganese oxides; includes bog manganese, asbolite, and lampadite. **Wenzelite**, $Mn_3(PO_4)_2.5H_2O$. **Willemite** (manganiferous), $(Zn,Mn)_2SiO_4$; troostite and tephrowillemite are varieties of willemite rich in manganese. **Winchite**, a blue manganiferous amphibole. **Withamite**, epidote with small quantity of Mn. **Wolframite**, $(Fe,Mn)WO_4$, iron-manganese tungstate. **Xantharsenite**, near chrondrarsenite, but contains more water. **Youngite**, $mZnS.nPbS.oMnS$. **Zincite** (manganiferous), $(Zn,Mn)O$.

It will be observed that manganese minerals may be associated with other minerals as isomorphous mixtures—*e.g.* in *sphalerite*, or *zinc blende*, $(Zn,Cd,Fe,Mn)S$; *zincite*, or *red zinc oxide*, $(Zn,Mn)O$; ferriferous or manganiferous *smithsonite*, or *calamine*, $(Zn,Fe,Mn,Mg,Ca)CO_3$; *manganocalcite*, $(Mn,Ca)CO_3$; *ankerite*, $5(Ca,Fe,Mn)(CO_3)_2.4Ca,Mg(CO_3)_2$; *botryogen*, $(Mg,Fe,Mn,Ca)_5(FeOH)_4(SO_4)_9.36H_2O$; *monimolite*, $(Pb,Fe,Mn)_3(SbO_4)_2$; *caryinite*, $(Mn,Ca,Pb,Mg)_3(AsO_4)_2$; *ottrelite* and *phyllite*, $(Al,Fe)_2(Fe,Mn,Ca,Mg)H_2Si_2O_9$; *ganophyllite*, $Pb_3(Ca,Mn)_2Si_3O_{11}$; *sphenoclase*, $(Ca,Mg,Fe,Mn)_6Al_2Si_6O_{21}$; etc. C. Benedicks [54] described a manganiferous garnet; J. Krenner, and K. Schlossmacher, a manganiferous *spinel*; etc.

According to G. Forchhammer, [55] manganese occurs in very many silicates as a tinctorial agent—*vide supra*—and in all iron ores. L. L. Fermor suggested that the iron-manganese ores be classified as follows : (i) *manganese ores* with 40 to 63 per cent. Mn, and 0 to 10 per cent. Fe ; (ii) *ferruginous manganese ores* with 25 to 60 per cent. Mn, and 10 to 30 per cent. Fe ; (iii) *manganiferous iron ores* with 5 to 30 per cent. Mn, and 30 to 56 per cent. Fe ; and (iv) *iron ores* with 0 to 5 per cent. Mn and 45 to 70 per cent. Fe. E. C. Harder has described the so-called **manganiferous iron ores**, which are mixtures of manganese and iron oxides in varying proportions— *e.g.* from less than one to more than 40 per cent. Mn. The iron is in the form of limonite or hæmatite, and the manganese is in the form of psilomelane or pyrolusite —rarely as carbonate. The high and medium grades are used for making spiegeleisen and ferromanganese, while the lower grade ore, with a small proportion of manganese, is used for making iron. There also occur **manganiferous silver ores** in the oxidized portions of the silver deposits of Western United States. The black,

amorphous ore consists of manganese and iron oxides and it carries silver chloride, and lead carbonate or an altered sulphide. The iron is present probably as limonite, and the manganese as wad. The iron oxide generally predominates over the manganese oxide, though at Butte the iron oxide is "almost entirely absent." Ores with a high proportion of silver and lead are smelted for these metals only when the manganese and iron oxides are valuable aids in fluxing. Ores with a low proportion of silver and lead, but with a high proportion of manganese and iron oxides, may be used for making spiegeleisen, ferromanganese, or iron alone when the proportion of manganese oxide is small. Ores too low in silver and lead for direct smelting, and too low in iron and manganese for making spiegeleisen or ferromanganese, are used as fluxes, when iron and manganese pass into the slag, while the silver and lead may be recovered in the smelting. Some **manganiferous zinc ores** contain franklinite, willemite, zincite, tephroite, or rhodonite along with iron and manganese oxides—e.g. the zinc ores of New Jersey. The ore is roasted to recover the zinc oxide, and the residuum is used for making spiegeleisen.

The commercial manganese ores are divided into three classes : the high-grade ores, bearing 35 per cent. or more of metallic manganese ; manganiferous iron ores, with 10 to 35 per cent. manganese ; and ferruginous ores, with 5 to 10 per cent. manganese. Manganese ores are quoted at so much per cent. per long ton. During 1924, the price of ore ranged from 1s. 9¾d. to 2s. 0d. per unit. The world's production in metric tons approximates :

1888	1896	1903	1910	1920	1924	1929
153,954	238,542	723,669	1,901,983	1,746,000	2,251,000	2,868,700

The production by countries is as follows :

	1888	1924	1928
Australasia	2,349	4,798	170
Bosnia, etc.	4,000	79,113	—
Brazil	—	159,229	359,651
British India	—	815,894	994,118

Other countries	3,114	—	2,144

D. A. Wells [56] found manganese to be present in nearly all igneous and metamorphic rocks. H. Moissan found that the pigment of the design on the wall of the grotto at La Mouthe is black on account of the presence of manganese oxide. Some objects found in the grotto are covered with a black deposit of manganese dioxide. F. W. Clarke estimated that the *limestone* of the earth's crust contains an average of 0·05 per cent. MnO. E. J. Chapman found manganese to be present

in many limestones ; W. Crum, A. Vogel, and L. Dieulafait, in *marbles*. The term *cipolin marbles* is applied to concretionary masses of limestone found in the lower parts of beds of gneiss, sometimes in large quantities, sometimes in isolated lenticular masses, and which are evidently contemporaneous with the rocks by which they are enclosed. L. Dieulafait detected manganese in over a thousand specimens of these marbles from different parts of the world. Water from the Atlantic Ocean, Indian Ocean, Red Sea, and the Mediterranean Sea, when allowed to stand in bottles for a month, furnishes a sediment containing manganese oxide ; this oxide is produced by the oxidation of the manganous carbonate in soln. Calcium carbonate is also formed. Hence, the calcareous mud from the bottom of the ocean forms chalk which contains manganese oxide. Indeed, fifty specimens of chalk from the Paris basin were found to contain more than fifty times as much manganese as the coloured marbles of the Pyrenees and Italy. L. Raab reported manganese in *chromite* ore and in *magnetite* ; R. Böttger, in *graphite* and *iodine* ; L. Picciardi, in the *volcanic ash* from Ætna ; and B. Platz found potassium permanganate in the masonry of a blast furnace. The purest of *clays* nearly always contain traces of manganese, while the ferruginous clays contain quite appreciable amounts. L. Azéma observed the presence of manganese in various coloured clays. F. B. Guthrie and L. Cohen found 0·254 per cent. Mn_2O_3 in some sterile *soils*. A. Contino found 0·03 to 0·48 per cent. Mn_3O_4 in various soils—sandy, volcanic, clay, and calcareous. P. de Sornay found 0·027 to 0·409 per cent. Mn in Mauritius soils ; O. M. Shedd found 0·005 to 0·331 per cent. MnO in the surface soils of Kentucky, and 0·002 to 0·260 per cent. in the subsoils. J. S. McHargue, G. Bertrand, A. Leclerc, and J. J. Skinner and M. X. Sullivan made observations on this subject.

C. W. Scheele observed the presence of manganese in commercial *alkali salts* and *potassium hydroxide* ; R. Böttger, in *potassium chlorate* ; J. Volhard, in *sodium hydroxide, red-lead*, and most *iron salts*, but not in ammonium ferric alum ; and R. Wegscheider, in *barium carbonate*.

G. Forchhammer [57] observed that sea-water contains manganese in soln. As indicated above, L. Dieulafait inferred that the manganese is present as manganous carbonate, and when the water is allowed to stand for a month, the carbonate at the surface in contact with air is converted into oxide, and precipitated ; at the same time, the calcium hydrocarbonate is converted into insoluble carbonate, so that a sediment of mixed calcium carbonate and manganese oxide is formed. The observations of J. Murray and co-workers, J. Y. Buchanan, C. W. von Gümbel, etc., on the formation of manganese oxide nodules in deep seas, etc., have been previously discussed. The manganese minerals readily undergo decomposition and pass into soln. when they are exposed to the action of surface waters ; and hence manganese finds its way into the rivers and seas. J. Murray estimated that one cubic mile of average river-water contains in soln. 5703 tons of manganese hemitrioxide, and that 6524 cubic miles of river-water are annually discharged into the sea. This means that 37,000,000 tons of the oxide, or nearly 26,000,000 tons of manganese, are brought every year by rivers into the oceans. This process has been going on for untold ages, so that a large proportion of manganese salts might be expected to be present in sea-water. This is not the case, for the manganese is deposited from sea-water and is found in the mud, etc., which deep-sea explorations have shown to be formed at the bottom of the ocean. D. A. Wells, and B. M. Lersch reported manganese to be present in numerous spring-waters. Thus, C. R. Fresenius reported it in the waters of Niederselters, Driburg, Langenschwalbach, Pyrmont, Ems, Homburg, and Wiesbaden ; J. Bouquet found traces in the waters of Vichy ; P. Berthier, St. Nectaire ; J. Löwe, Krouthal, Nassau ; C. Bromeis, at Nauheim ; J. J. Berzelius, H. Göttl, and F. Ragsky, Carlsbad ; G. Wolf, Gastein ; A. von Planta, Ragaz-Pfäfers ; E. Ludwig, Srebremica, Bosnia ; and Karlsbrunn, Austrian Silesia ; M. Gläser and W. Kalmann, and R. Nasini and co-workers, Roncegno, Southern Tyrol ; C. F. Eichleiter, Orsola, Southern Tyrol ; A. Goldberg, Bad Elster, Saxony ; E. Bechi, Acqua delle piazzuole des Arnotals ; C. A. H. von

Wolzogen - Kühr, Amsterdam; S. de Luca, Pozzuoli, Italy; G. Lunge and R. E. Schmidt, St. Lorenzquelle, Leuk, Switzerland; A. Carnot, Aveyron, France; F. Jadin and A. Astruc, Vichy, Luxeuil, and Bussang in the Vosges, the Alps, Montagne Noire, the plain of Languedoc, and Boulou, France; C. H. Bothamley, Harrogate and Askern, Yorkshire; B. A. Burrell, Knaresborough, Yorkshire; T. E. Thorpe, Cheltenham, England; and C. du Ponteil, Hot Lake, White Island, New Zealand; E. H. S. Bailey and F. B. Porter, a trace in the artesian well of Abilene, Kansas; W. P. Mason, Missouri Springs, Missouri; A. H. Wiebe, Mississippi river; W. F. Hillebrand, Shoal Creek, Missouri; Mountain View Mine, Montana; and La Junta, Colorado; J. K. Haywood, F. A. Gooch and J. E. Whitfield, Hot Springs of Arkansas, and the Excelsior Geyser, Yellowstone National Park; M. B. Harden, Rockbridge Alum Spring, Virginia; and F. G. Novy, salt springs of Texas. S. Yoshimura studied the variation in the manganese content of the water of Takasuka-Numa, Saitama, during periods of stagnation, and circulation. M. Weibull found 23 mgrms. MnO per litre of water from Lund, Sweden; the quantity of other mineral matters present was not particularly large. *Chrenothrix manganifera* was present in the water and caused the manganese to be deposited in the water-pipes to such an extent as to block them. The formation from which the water came consisted principally of gneiss in which were veins of diorite containing 8·2 per cent. of manganous oxide. C. A. H. von Wolzogen-Kühr found 0·3 parts of manganese per million in the water of the Oranjekom and canals of Amsterdam, and 0·1 per cent. in the mud. The oxidation of manganese compounds by the oxygen of the air does not occur with an acidity of $p_H=8\cdot1$; and manganese bacteria can oxidize dissolved manganese not only in alkaline soln., $p_H=10$, but also in acidic soln., $p_H=4$ to 5. Manganese has also been reported as a common constituent in the deposits from various springs, etc. Thus, H. Braconnot observed it with the springs of Luxeuil, Vosges; C. M. Kersten, in a mine-water at Freyberg; E. F. Leuchs observed a large mass of hydrated manganese oxide in the water channel of Nürnberg; R. W. Townsend, in the discharge from a spring at 44° near Cape of Good Hope; C. M. Kersten, at Carlsbad; E. H. S. Bailey, in the city water-pipes of Hutchinson, Arkansas Valley; R. Woy, O. Materne, and E. von Raumer reported cases of obstruction in service water-pipes by manganiferous deposits.

G. Forchhammer [58] found that manganese is present in the ashes of the *Zostera marina*, and E. J. Maumené observed manganese in the ashes of the *Fucus serratus*. C. W. Scheele found manganese to be present in wood ashes, and a little in the ashes of thyme—*Thymus serpillum*; G. Forchhammer, in the ashes of the *Padina pavonia*; T. J. Herapath, in the ashes of the radish, turnip, beetroot, and carrot; E. O. von Lippmann, the vinasse from a beet-sugar factory; T. Richardson, sugarcane; W. F. Salm-Hortsdar, oats; J. von Liebig, tea and coffee; R. Böttger, and A. Domergue and C. Nicolas, in tea—0·022 to 0·065 per cent.; L. L. Fermor, bamboo; F. A. Flückiger, and E. F. von Gorup-Besanez, the water-chestnut— *Trapa natans*; G. Campani, wood, corn, and tobacco; R. Böttger, beech, box, and cork; F. P. Dunnington, corn; J. E. de Vrij, beech-nuts; J. A. Trillat, in vegetables; M. Balland, in potatoes; and J. S. McHargue, in the pericarp and germ of rice, barley, wheat, tomatoes, oranges, and lemons. Observations were also made by A. Hafner and H. Krist, and W. P. Headden. N. Passerini found 0·068 per cent. of manganese in dried *Lupinus albus*; the different parts of the plant, dried at 100°, contained the following proportions of ash, and the indicated percentages of manganese in the ash—the first column for legumes refers to those separated from the middle of the plant, and the second column to those from the ends:

	Leaves.	Legumes.		Stems.	Branches.	Seeds.	Roots.	Nodules.
Ash	8·267	3·726	3·280	2·286	2·021	2·102	3·910	10·400
Mn_3O_4	12·436	7·080	5·927	4·580	4·231	2·190	1·536	0·377

Unlike P. Pichard, F. Jadin and A. Astruc did not find manganese to be most

concentrated in the parts of a tree which are in vegetative activity, provided the percentages are not calculated on the weight of ash, but on the dried organs. In that case, more manganese is present in old leaves than in young leaves. They also found more manganese in the aerial portions than in the roots. G. Bertrand and M. Rosenblatt found that in one group of plants, the manganese content of the leaves is at a maximum at the commencement of the leaf formation, and then diminishes with age, the rate of diminution differing with the group. In another group, the manganese content increases very rapidly with age to a maximum, and then diminishes. In another group, the manganese content increases continuously with age. D. H. Wester found manganese present in various flowers, free from dust and selected in dry weather; and also in the seeds of 48 species of plants. C. C. McDonnell and R. C. Roark found little difference in the stem and flowers—open and closed—of the *Chrysanthemum cinerariæfolium*. According to J. S. McHargue, the proportion of manganese present in the hazel nut varies considerably in different parts of the same seed, and the seed coat surrounding the kernel contains a much larger proportion than the kernel or the outer coats. There is a close connection between the amount of manganese and the presence of oxydases in plant tissues, and it is therefore considered probable that the accumulation of manganese in the seed-coat bears an important relation to the vital processes in the formation and germination of seeds. L. E. Westman and R. M. Rowat found that in the *Rhamnus purshiana* (cascara sagrada) the proportion of manganese in the inner third of the bark is about twice as great as in the outer third. When the powdered drugs of the *Rhamnaceæ* family are extracted with water, approximately one-fourth of the manganese goes into solution. G. Bertrand and M. Rosenblatt found that with the *Nicotina rustica* and *Lilium lancefolium* those organs in which chemical changes are the most intense contain the highest percentages of manganese. The seeds contain a high proportion of manganese, doubtless for the use of the future seedling.

E. J. Maumené found manganese to be present in potatoes, wheat, rye, barley, rice, sorrel, beans, sugar beet, carrot, lentils, peas, asparagus, different kinds of fruit, fodder, cocoa, coffee, and tea; but more in lemons, oranges, onions, and garlic. G. Bertrand and M. Rosenblatt found manganese in those plants in which E. J. Maumené found none. Hence, *the presence of manganese is general in all the organs and species of plants so far examined.* G. Bruni and C. Pelizzola found manganese dioxide in raw caoutchouc. F. Jadin and A. Astruc also found manganese in the ash of lucerne, sainfoin, vetches, clover, potatoes, mangolds, poplar leaves, chestnut, rice, maize, barley, oats, bran, and meadow-hay. J. S. Jones and D. E. Bulles found 42 mgrms. per kilogram of air-dried vetch; 33 in red-clover; 68 in Alsike clover; 32 in lucerne; 33 in field-peas; 27 in sweet clover; and 34 in white clover. More was present in the leaves than in the other parts. H. Marcelet observed no relation between the proportion of arsenic and manganese in sea-water plants. L. E. Westman and R. M. Rowat found manganese in the ash of many laxative drugs—alder buckthorn bark, cascara sagrada, cassia bark, podophyllen root, senna leaves, rhubarb root, *Rhamnus californica* bark, liquorice root, jalap root, wahoo bark, cassia pulp, and Barbadoes aloes; and J. S. McHargue, in spear grass. E. J. Maumené found 0·0001 to 0·0020 grm. per litre in thirty-one wines of different European and African vintages. O. Prandi and A. Civetta found that wines contain 0·53 to 1·65 parts of manganese per million; the wines of better quality usually contain the highest proportion. G. Massol observed that mistelles —fortified musts—contain from 0 to 0·010 grm. MnO per litre. A. Hilger, and L. Rössler found 0·3 to 0·8 per cent. of manganese in the ash obtained from wines; L. Medicus found bilberry wine specially rich in manganese; and A. Alessi observed manganese in some residues in ancient wine-glasses. J. Kachler found that the manganese is present as manganese oxalate in the cambial sap of the pine; and G. Campani observed that it is present in plant-ashes as oxide, silicate, or phosphate. G. Guérin found that when wood-sawdust is macerated for two or three

days with a one per cent. soln. of potassium hydroxide, a deep brown liquid is obtained, and when this is acidified with hydrochloric acid, a bulky, flocculent precipitate is produced. This precipitate can be washed with very dil. hydrochloric acid, redissolved in ammonia, reprecipitated by acid, washed and dried. It is a pale brown powder, which, when obtained from the beech, had the composition, C, 52·762 ; H, 5·04 ; N, 4·60 ; S, 0·666 ; P, 1·297 ; Mn, 0·402 per cent. According to G. Bertrand, all manganese salts have the property of bringing about the oxidation by atmospheric oxygen of solutions of quinol, pyrogallol, and paraamidophenol, guaiacum, and similar substances. The soln. acquires a colour which depends on the nature of the carbon compound, whilst the intensity of the coloration depends on the nature of the acid in combination with the manganese. Oxidation is much more energetic with salts such as the succinate, gluconate, or salicylate than with the chloride, sulphate, or nitrate. He inferred that the oxydases are special compounds of manganese in which the acid radical, of a proteid character and varying with the particular ferment, has just sufficient activity to keep the metal in soln., whilst the metal is the real carrier of oxygen. The subject was discussed by A. Villiers, A. Livache, and J. S. McHargue.

Animals feed on plants, directly or indirectly, and the presence of manganese might therefore be expected in animal tissues. G. Forchhammer [59] found manganese in sea-organisms. L. N. Vauquelin, and J. McCrae detected manganese in hair ; J. J. Berzelius, in bone ; A. Béchamp, in the liver ; H. Oidtmann, in the human liver and spleen ; J. S. McHargue, in the liver, kidney, and pancreas. P. Pichard found less manganese in animals than in plants ; less in bones than in flesh ; less in flesh than in an egg ; and less in the white of egg than in the yolk ; E. Pollacci, in the human milk and the milk of house animals ; E. J. Maumené, in urine, bones, hair, and the fæces of man ; F. von Oefele, in the excrement of man ; and E. N. Horsford, in the normal urine of man. J. S. McHargue found colostrum to be richer in manganese than ordinary milk. The tissues of cod-liver, fish roe, and the yolks of eggs are rich in manganese, whilst purified cod-liver oil and the whites of eggs contain negligibly small amounts. E. J. Maumené observed no manganese in human blood, but a contrary result was obtained by E. Cottereau, B. du Buisson, N. A. E. Millon, and A. Riche, for they found 1 to 5 mgrms. per kilogram in the blood of human beings and animals ; while G. Bertrand and F. Medigreceanu found that human blood does not contain more than 0·02 mgrm. per litre ; and the amount in the blood of horses, oxen, pigs, rabbits, ducks, and hens is about the same, whilst that in sheep does not exceed 0·06 mgrm. per litre. Most of the manganese occurs in the plasma ; the element is not present in hæmoglobin. P. Carles said that the human blood contains a trace of manganese, but the metal is not present in the blood of oxen, rabbits, fowls, or ducks. Somewhat larger quantities are present in the liver and kidneys, and still more is present in the hair and nails. G. Campani found manganese in the serum and blood corpuscles of the ox. E. J. Maumené, and M. E. Chevreul found manganese in mutton-fat. J. S. McHargue considers that manganese is contained in those plant and animal tissues richest in *vitamins*, and a relationship exists between this element and the vital factors contained in these tissues. H. C. Bradley found 0·6 to 1·2 per cent. of manganese in the tissues and eggs of fresh-water clams, unio, and anodonta —the manganese is most abundant in the gills and mantle. This element is said to be necessary for vital activity, since mussels cannot live in lakes poor in manganese and in the crenothrix and diatoms which contain large amounts of manganese and which form the food of mussels. G. Bertrand and F. Medigreceanu found manganese from hundredths to tenths of a mgrm. in 100 grms. of the digestive, respiratory, and genito-urinary organs, glands with internal secretion, muscular, nervous and osseous tissue, skin and teeth, adipose tissue, eyes, and finally the bile, milk, or eggs of typical animals of the three classes, mammals, birds, and fishes—but not in the white of birds' eggs. For similar organs of the same species the variation in manganese content is very slight from one animal to another, and

is but little greater amongst different species of the same class. The difference is, however, more marked from class to class, birds having a higher manganese content than mammals. Amongst the more important organs or tissues, the manganese content is highest in the uterus of birds (0·786–2·20 mgrms. per 100 grms.), the lowest value occurring in the muscular and nervous tissues and the lungs. The grey matter of ox brain has a higher manganese content than the white matter; the heart and the muscles of the tongue than the muscles of the trunk and limbs. Milk is very poor in manganese, although slightly richer than blood. They found that of the invertebrata the gastropod molluscs and the lamellibranchia are the most abundantly supplied with manganese. The animal kingdom as a whole is, however, very poor in manganese as compared with the vegetable kingdom. J. Cotte observed manganese in various sponges, particularly in the gemmules. H. M. Fox and H. Ramage found manganese in nineteen species of polychaetes; it was widely distributed in the molluscs, being found in all the organs of the land gastropods; it was found in many organs of the marine gastropods, but was absent from *Haliotis*. E. F. Hopkins found that manganese is necessary for the growth of *Chlorella*.

§ 3. The Preparation of Manganese

The manganese ores as mined may require a preliminary concentration or cleaning. Ores containing rock fragments and clay impurities can be dried and the clay pulverized by passage through a revolving drum, and the clay removed by a revolving screen. The coarse manganese and waste can then be passed to a picking belt, when a separation is made. Free silica can be removed by washing. The method of concentrating low-grade ore, however, depends on the nature of the ore. High-grade ores may require no preliminary treatment. The commonest ores are manganese oxides, carbonates, or silicates.[1]

F. Staaden and C. Heinzerling proposed to treat ores with a small proportion of manganese with water containing magnesium chloride or oxychloride, with hydrochloric acid, or with gaseous hydrogen chloride, so that soluble manganous chloride is formed. W. Diehl said that hydrochloric acid is the best solvent. F. Staaden and C. Heinzerling said that ferruginous ores are best treated with sulphur dioxide so as to convert the manganese into sulphate, and subsequently into chloride, by treatment with calcium or magnesium chloride. The Deutsche Solvay-Werke roasted the ore with ferric oxide and alkali carbonate, and leached out the manganate—*vide infra*, the manganates. F. Staaden heated a powdered mixture of the ore with pyrites, and A. G. Friedrichssegen, a mixture with spathic iron ore and zinc blende. In both cases the manganese compounds were removed by extraction with water. In J. T. Jones's process, examined by P. Christensen and W. H. Hunter, the ore is subjected to a low temp. reduction to form metallic iron and a slag. The manganiferous slag is then smelted for a manganese alloy. These methods cannot compete with the simpler process required when high grade ores are employed. Until comparatively recently, manganese was *une curiosité de laboratoire*, but when the valuable properties which it imparts to some alloys were recognized, it became one of the world's important metals. Indeed, ordinary

commercial steel cannot be satisfactorily manufactured without its quota of manganese—say 0·4 to 1·0 per cent. Mn.   A. G. Betts heated the silicate ore with iron sulphide, to form metallic iron, manganese sulphide, and a ferrous silicate slag.   The manganese sulphide layer is then treated for manganese.   Manganese has been prepared by the following processes :

The reduction of oxides, etc., by carbon.—The early workers—*vide supra,* the history of manganese, J. F. John,[2] P. Berthier, M. Faraday, etc.—prepared manganese, contaminated by more or less carbide, by mixing manganese oxide and powdered carbon with oil, and pressing the pasty mass into a charcoal crucible ; the mixture was then covered with charcoal and a lid luted on the crucible. The whole was then heated in a blast furnace for an hour.   The metal was purified by melting it under borax.   According to H. C. Greenwood, reduction of the oxide by carbon begins at 1105°.   H. St. C. Deville reduced the oxide with sugar charcoal, using, as recommended by J. F. John, rather less carbon than is needed for the reduction, so as to avoid, as much as possible, the production of carbide. H. Tamm recommended the carbon reduction using a flux of soda-lime, glass, and fluorspar, and purifying the product by fusing it with half its own weight of manganese carbonate.   The product contained 99·91 per cent. Mn.   H. V. Regnault, J. Mason and A. Parkes, and L. Troost and P. Hautefeuille used a similar process. A. Valenciennes employed a crucible lined with magnesia for the reduction. J. E. Loughlin used potassium cyanide, and animal charcoal as the reducing agent.   H. Moissan heated a mixture of manganese oxide and carbon in an electric arc furnace for a few minutes.   The metal contained 6·35 to 14·59 per cent. of carbon ; but if the reduction is effected in the presence of an excess of oxide, as little as 3·6 per cent. of carbon may be present as carbide.   If the heating be too intense, or too long, the yield may be small, owing to the volatilization of the metal.   To guard against too intense a heating the mixture was reduced in a carbon crucible closed by a lid.   E. W. Hopkins proposed to make the metal free from carbon by forcing the vapour of the metal—obtained by heating a mixture of the metal oxide and charcoal—through a layer of oxide.   If alloys are desired, say a manganese-copper alloy, the vapour of the manganese can be passed through a layer of copper oxide.   J. W. Cabot and S. W. Vaughan heated high grade ferromanganese in a blast furnace with a mixture of 100 parts of bessemer slag, 60 parts of coke, and 60 parts of limestone.   A. Sternberg and A. Deutsch reduced oxy-compounds of manganese and the alkaline earths by carbon at 1000° to 1400°. C. M. J. Limb reduced psilomelane—native barium manganite—by carbon at a high temp., and employed the by-product for making barium carbide.   R. Saxon reduced manganese oxides by calcium carbide.   E. G. L. Roberts and E. A. Wraight discussed the elimination of carbon by heating the carburetted metal and manganese oxide above 1670°, at which temp. the reaction $Mn_3C+MnO=4Mn+CO$ occurs. G. E. R. Nilson discussed this subject.   H. H. Meyer reduced manganous oxide, silicate, and phosphate in the blast furnace.

The reduction of the oxides by metals, etc.—C. and A. Tissier showed that although powdered aluminium reduces many metal oxides, sometimes with explosive violence, it does not reduce the oxides of zinc and manganese.   On the other hand, W. H. Greene and W. H. Wahl obtained the metal by heating a mixture of manganese oxide with metallic aluminium or magnesium and a flux of cryolite or fluorspar in a crucible lined with lime or magnesia.   J. Debuigne, and F. L. Garrison used a similar process.   In H. Goldschmidt's thermite process, a mixture of manganese oxide and coarsely powdered aluminium, in a crucible, is ignited by a piece of magnesium ribbon surrounded by a little barium dioxide.   The resulting metal is free from carbon, but it contains silicon, iron, etc.   To avoid undue contamination with aluminium, the oxide is kept in slight excess.   This process is employed industrially.   F. Fujibayashi recommended a mixture of manganese tritatetroxide 100, and manganese dioxide 15 to 20, along with 90 per cent. of the calculated amount of powdered aluminium—the yield was 85 to 90 per cent. of the theoretical.

M. L. V. Gayler obtained manganese of 99·3 per cent. purity by reducing the purified oxide with purified aluminium—the thermite process—and then distilling it in a quartz vessel under reduced press. Commercial manganese prepared by the thermite process may have 0·09 per cent. S ; 0·65 to 1·61, Si ; 0·02 to 0·12, C ; 0·94 to 1·82, Fe ; 0·29 to 0·79, Al ; 0·08, P ; 0·15, Cu ; and 96·45 to 98·0, Mn. P. Lebeau found as much as 5·25 per cent. of silicon in manganese prepared by the thermite process. J. H. Brennan used the silico-thermic process. L. Weiss and O. Aichel reduced the oxide by heating it with mischmetall. S. Heuland melted the manganese ore in an electric furnace with a reducing agent sufficient to furnish only a small proportion of metal. This metal will contain all the deleterious impurities in the ores, *e.g.* phosphorus, carbon, or iron. The remainder of the metal is then reduced from the fused slag by heating it with calcium silicide.

The reduction of halogen salts by metals.—E. Frémy prepared manganese by passing the vapour of sodium over red-hot manganese chloride. C. Brunner heated in a crucible a mixture of two parts of manganese fluoride or chloride and one part of sodium covered with a layer of sodium chloride and fluorspar. The product was purified by fusing it under sodium chloride to which a little potassium nitrate or chlorate had been added. C. Bullock, and J. E. Loughlin also used the sodium reduction process. W. Diehl also reduced the double sodium or potassium manganese chloride, R_2MnCl_4, with sodium. E. Glatzel prepared manganese by heating a mixture of finely-divided, anhydrous manganese chloride (100 grms.) and dry, powdered potassium chloride (200 grms.) in a covered Hessian crucible until it just melts, and then adding magnesium (15 grms.) in portions of 3 to 4 grms. at intervals of 2 to 3 minutes ; if the fused mass is too hot a very violent reaction occurs, and the contents of the crucible are thrown out. The crucible is covered again, heated more strongly, and then allowed to cool slowly in the furnace. The yield of manganese is 20 to 25 grms., the metal containing traces only of silica and being quite free from magnesium.

The reduction of solutions of manganese salts by metals.—W. B. Giles obtained the metal by treating a soln. of manganous chloride with sodium amalgam. Hydrogen is evolved, and an amalgam of manganese is formed. This is quickly washed, and dried. When the amalgam is heated in a tube, closed at one end, the mercury is driven off, and powdered manganese remains. H. D. Royce and L. Kahlenberg recommended heating the amalgam to dull redness in a current of hydrogen, so as to prevent the oxidation of the manganese as the mercury is driven off. The powder can then be melted in an atm. of hydrogen. According to G. A. Maack, and T. L. Phipson, manganese can be precipitated from a neutral soln. of manganese chloride or nitrate by means of magnesium. On the other hand, Z. Roussin, and A. Commaille obtained only manganese hydroxide by this method ; and S. Kern showed that manganosic oxide is formed in two stages : $3MnCl_2+3Mg+3H_2O=3MnO+3MgCl_2+3H_2$; and the manganous oxide is oxidized by water : $3MnO+H_2O=H_2+Mn_3O_4$. Similar results were obtained by D. Tommasi, and K. Seubert and A. Schmidt with soln. of manganese sulphate and chloride ; while H. N. Warren said that the metal is precipitated by magnesium, wrapped round with a few coils of asbestos paper, from soln. of manganese acetate. J. G. Hibbs and E. F. Smith tried the action of magnesium on aq. soln. of manganese chloride in the presence of alcohol and of a mixture of alcohol and ether, so as to hinder the oxidation of the manganese. The deposit contained a kind of hydrated oxide ; the presence of free manganese was not proved. The presence of mercury in W. B. Giles's experiment hinders the oxidation of the precipitated manganese by water by forming an amalgam. J. A. Poumarède reported that zinc will precipitate manganese from soln. of its salts, but probably the same remarks apply here as in the case of magnesium. According to G. A. Maack, aluminium has very little action on cold soln. of manganese salts, but with warm soln. of the sulphate or chloride manganese is precipitated ; there is very little action with soln. of the nitrate.

Electrolytic processes.—R. Böttger, C. Luckow, and W. Wernicke observed that manganese is deposited as a hydrated peroxide or a permanganate is formed when the neutral or acidic soln. is electrolyzed. G. Gore electrolyzed fused manganous fluoride and also a dil. soln.; in the former case the black deposit on the cathode was not manganese. R. Bunsen obtained manganese by the electrolysis of an aq. soln. of manganous chloride, using platinum electrodes. If the current be too low, manganosic oxide is deposited. T. Moore obtained manganese by the electrolysis of a neutral soln. containing a large excess of ammonium thiocyanate, and a current of high density; and E. F. Smith and L. K. Frankel found that the metal is deposited greyish-white and compact from soln. containing an excess of potassium thiocyanate. P. P. Fedotéeff found that under the most favourable conditions, with a neutral or weakly acid $6.5N$-soln. of manganous chloride, at 5°, and a current density of 20 amps. per sq. dm., the deposit on the copper cathode contained about 65 per cent. of manganese and 35 per cent. of hydrated oxide. According to G. D. van Arsdale and C. G. Meier, manganese can be obtained by the electrolysis of a neutral molar soln. of manganous sulphate at 23°, with electrode densities of 1 to 4·6 amps. per sq. dm., and they obtained current efficiencies of 73 to 89 per cent. (Fig. 3). The maximum occurred with about 2 amps. per sq. dm. Using a current
density of 0·9 amps. per sq. dm., and with increasing acidity, the current efficiency fell rapidly, almost linearly, becoming zero with 0·36 per cent. H_2SO_4 (Fig. 4). A. J. Allmand and A. N. Campbell showed that the deposits of manganese obtained under these conditions are very impure; they also observed that the deposition of manganese ceases with soln. containing 0·36 per cent. H_2SO_4; and that manganese of a high degree of purity and in a coherent form can be prepared in small amounts by using a catholyte containing 300 grms. of manganous sulphate tetrahydrate, 100 grms. of ammonium sulphate, and 2·5 grms. of sulphuric acid per litre, the acidity being maintained by suitable additions of acid. Using a rotating cathode, current efficiencies of 50 to 60 per cent. were obtained. Using a standard electrolyte of ammonium and manganous sulphates, no marked improvement was obtained with additions of gum arabic, dextrin, and gelatin, and the deposit was less pure. Using a burnisher on a rotating electrode, the current efficiency was reduced to 8·6 per cent. The use of thiocyanate as electrolyte gave a more coherent but more impure deposit; and the use of manganese and ammonium perchlorates gave a catholyte which rapidly hydrolyzed. Hydrogen dioxide, potassium chlorate, nitrobenzene, and cinnamic acid were tried as depolarizers, but their effect on the cathode deposit was nugatory. They found that the best conditions for the electrodeposition of pure manganese consist in the electrolysis of a soln. containing manganous and ammonium sulphates (the catholyte) separated by a diaphragm from the anolyte (ammonium sulphate soln.), the H·-conc. being kept at 10^{-6} to 10^{-8} by the regulated addition, as required, of sulphuric acid or of ammonia. The temp. is 30° and the current density at the cathode 10 to 15 amps. per sq. dm. The rotating aluminium cathode has a burnisher lightly pressing against it. The subject was discussed by C. N. Otin, H. Bardt, and J. Brezina.

A. Guntz prepared the amalgam by the electrolysis of a conc. soln. of manganous chloride, using a mercury cathode. The amalgam was rapidly washed, passed through leather, dried, and distilled in vacuo at 200° to 250° to remove the mercury. A similar process was used by W. Diehl, and H. Moissan. O. Prelinger obtained the amalgam by passing an electric current—11 volts and 22 to 23 c.c. of electrolytic gas per min.—from a mercury cathode (20 c.c.) through a sat. aq. soln. of 75 c.c.

FIGS. 3 and 4.—The Effect of Current Density and of Acidity of Solution on the Deposit of Manganese.

of manganous chloride to an anode of carbon or platinum-iridium contained in a porous vessel. The temp. rises to 70°, and after 5 to 6 hrs. the mercury assumes a pasty consistency. The paste is quickly washed by running water without undergoing appreciable decomposition, the excess of mercury squeezed out through linen, and the residue dried over calcium chloride in an atm. of hydrogen. The mercury was distilled off. E. Kuh employed a similar process, and melted the powder in a magnesia boat in vacuo, and also distilled the metal, obtaining it as a *wunderschöne metallische Kruste*. M. L. V. Gayler obtained 99·99 per cent. manganese by distilling the metal above its m.p. at 1 to 2 mm. press.; and J. B. Friauf said that the process is impracticable because of the great losses. H. S. Booth and M. Merlub-Sobel prepared the metal by the electrolysis of a soln. of manganous thiocyanate in liquid ammonia.

A. Simon obtained manganese by dissolving a lower oxide of manganese or ferromanganese in fused calcium fluoride, alone or mixed with other fluorides to make it more fusible. The metal is freed from phosphorus and silicon by the action of fluorine on the carbon anode, whereby carbon tetrafluoride is formed, which reacts with silica : $SiO_2+CF_4=CO_2+SiF_4$; and manganese phosphide reacts : $2P_2Mn_3+3Mn+3CF_4=4PF_3+3Mn_3C$; and the phosphorous fluoride also reacts with silica : $3SiO_2+4PF_3=3SiF_4+P_4O_6$. G. Neuendorff and F. Sauerwald obtained the metal by the electrolysis of the fused silicate.

Ferromanganese was formerly made in crucibles ; H. H. Meyer [3] discussed the manufacture of manganese in blast-furnaces similar to those used for making pig-iron. The manufacture was discussed by W. Henderson, T. L. Joseph and co-workers, P. M. Tyler, H. Thaler, R. M. Keeney, J. E. Stead, F. Kohn, A. Pourcel, H. Bessemer, W. Armstrong, etc. The manufacture of ferromanganese in electric furnaces was described by E. S. Bardwell, C. D. Grier, J. W. Richards, F. Sauerwald and G. Neuendorff, G. Neuendorff, G. Gin, etc.—*vide* iron and manganese alloys.

J. Strong and C. H. Cartwright [4] prepared **mirrors** or thin films of manganese by condensation from the vapour. V. Kohlschütter and J. Tüscher prepared aerosols or **colloidal manganese** by vaporizing the metal in the arc, and suddenly condensing the vapour in air ; T. Svedberg, by spluttering in *iso*butyl alcohol, ether, etc. ; and H. Kuzel, by the trituration of the mechanically or electrically subdivided metal alternately with acidic and alkaline soln.

§ 4. The Physical Properties of Manganese

The properties of manganese described in the literature differ, showing that the impurities which characterize the metal obtained by different processes modify many of the properties. The metal prepared by reducing the halide with sodium in C. Brunner's [1] process was reported by C. Bullock to be steel-grey, brittle, and so hard that a file will not scratch it, and it will scratch glass ; whereas the metal prepared by H. Goldschmidt's process is said to resemble iron but to have a reddish tinge ; it is also said to be hard and brittle, but not to scratch glass. The metal obtained by distilling mercury from the amalgam at a dull red-heat was

described by O. Prelinger as a grey, porous, non-pyrophoric mass which is readily reduced to powder. E. Frémy regarded his specimen as crystalline, and R. Bunsen also said that the electrodeposited metal is crystalline. M. L. V. Gayler described the metal electrodeposited at 27° as a bright, silver-grey mass, and that desposited at 34° is also bright and silver-grey. It shows treeing at the edges of the cathode and in isolated patches. The distilled 99·99 per cent. manganese is silver-grey in colour, and is very brittle. When the distillate is melted down into ingots, numerous cracks appear in the cooling ingot. These cracks cause the ingot to fall to pieces with the slightest press., and they are associated with a transformation in the metal, and not with the normal shrinkage. The specimens when polished and etched with 6 per cent. alcoholic nitric acid, or 0·5 per cent. alcoholic hydrochloric acid, show numerous cracks ; and if tempered by heat, the sample is liable to crumble to pieces when quenched, or when treated with the etching fluid. Some changes in the crystalline structure have been observed to occur about 742°, but no perceptible change occurs at 682°. A marked change in vol. occurs about one or both these temp.

P. Groth placed manganese in the list of elements which form cubic crystals, apparently because M. Levin and G. Tammann found that it yields a continuous series of isomorphous mixtures with iron. Attempts by A. W. Hull and W. P. Davey, and J. F. T. Young to determine the crystal form from the **X-radiograms** were not successful, for the pattern obtained appeared to be too complex for the cubic system. A. Westgren and G. Phragmén, however, inferred that manganese exists in at least three **allotropic forms**—*vide infra*, magnetic susceptibility. There is a-manganese which is stable at ordinary temp. and gives an X-radiogram corresponding with the cubic system, and at higher temp. this changes into β-manganese, which is also cubical, but slightly denser ; whereas electrolytic manganese is tetragonal, with the same sp. gr. as a-manganese. It is designated γ-manganese ; whereas A. J. Bradley called it a-manganese, and A. Westgren and G. Phragmén's a- and β-form were called respectively the β- and γ-forms. A. J. Bradley and J. Thewlis found that for ordinary manganese the cubic lattice has $a = 8.894$ A. There are 58 atoms per cell. Each lattice point has a cluster of 29 atoms, and the clusters have tetrahedral symmetry. The interatomic distances range from 2·25 A. to 2·95 A. and indicate an unequal distribution of electrons. A. J. Bradley showed that the a- and β-forms are normally present in commercial manganese, and that the a-form is stable in the range 150° to 180°, and the β-form is stable above 650°. Both forms are stable within the range 650° to 850°, and the phenomenon corresponds with isodynamic allotropy, because there is a definite equilibrium mixture of the two allotropes corresponding with each temp. J. D. Bernal favoured this interpretation, but not so E. Persson and E. Oehman, and A. J. Bradley said that the pure β-form of manganese is obtained by raising the temp. above 850° in vacuo, and suddenly quenching ; whereas the pure a-form is difficult to obtain by heat treatment alone, although it is produced when the β-form is sublimed in vacuo. It has not been possible to interpret the X-radiograms of the a- and β-forms of manganese, but the low order of symmetry suggests the monoclinic or rhombic systems. The third allotropic form, γ-manganese,

FIG. 5.—Model of Space Lattice of a-Manganese with $a = 8.89$ A.
FIG. 6.—Model of Space Lattice of β-Manganese with $a = 6.29$ A.

has been obtained only by electrodeposition. The X-radiograms correspond with a body-centred, tetragonal lattice with the axial ratio $a : c = 1 : 1.34$, or a face-centred tetragonal lattice with the axial ratio $a : c = 1 : 0.9445$. Assuming the face-
centred lattice, the edges of unit cell are $a=3.764$ A., and $c=3.556$ A. The volume of unit cell, containing 4 atoms, is 50.3×10^{-24} c.c., so that each atom occupies 12.58×10^{-24} c.c. The weight of one atom is 90.6×10^{-24} grm., and the corresponding density of manganese is 7.21. The distances of closest approach of atoms for manganese, iron, cobalt, and nickel are respectively 2.59, 2.54, 2.51, and 2.50 A. On heat treatment, γ-manganese passes into the α- and β-forms, but the change does not appear to be reversible. G. D. Preston found single crystals of α-manganese had a body-centred, cubic lattice with $a=8.894$ A., and a density of 7.44; while β-manganese, stable above 742°, also formed cubic crystals with a lattice of side $a=6.29$ A., containing 20 atoms. The results of G. D. Preston are summarized in Figs. 5 and 6. Observations were made by S. von Oldhausen, A. Karlsson, T. Ishiwara, and A. Osawa.

Working with distilled, 99.99 per cent. manganese, M. L. V. Gayler observed arrests on the cooling curve 1195°, 1005°, 740°, and 681°; and on the heating curve there is a change of direction at 684°, and arrests at 740°, 744°, 1043°, and 1188°. S. Umino found arrests at 835° and 1044°. She concluded that only one of the two lower critical temp., 742°, is accompanied by a change in physical structure; no such change is apparent at 682°. It is generally taken that 742° is the transition point of the $\alpha\rightleftharpoons\beta$ change. C. H. M. Jenkins and M. L. V. Gayler studied this subject. According to E. Persson and E. Oehman, pure manganese when quenched gives nothing but β-manganese, but if manganese be alloyed with some copper, iron, nickel, or cobalt, the m.p. curves are unbroken, and the alloys have a face-centred, cubic lattice. Alloys of manganese with even less than 5 per cent. of copper have a face-centred, tetragonal lattice. The higher the copper content the more does the structure approximate to the face-centred, cubic lattice, thus :

Copper	3.8	8.2	10.5	15.0 per cent.
a	3.771	3.765	3.763	3.755
c	3.556	3.601	3.617	3.660
$a:c$	1 : 0.943	1 : 0.956	1 : 0.961	1 : 0.975

By extrapolation the values for manganese alone become $a=3.776$, $c=3.525$, and $a:c=1:0.934$. These values agree closely with those obtained by A. Westgren and G. Phragmén. The high temp. phase obtained by quenching these alloys and the γ-manganese obtained by electrolysis are the same. By plotting the maximum manganese content in the γ-phase at different temp., the transition point of $\gamma\rightleftharpoons\beta$-manganese approximates 1191°. With iron and nickel alloys the γ-phase can be obtained only by quenching from temp. exceeding 1024°; and for an alloy with 21.8 per cent. of iron, $a=3.705$, $c=3.619$, and $a:c=1:0.976$; whilst with an alloy having 15.7 per cent. of nickel, $a=3.736$, $c=3.606$, and $a:c=1:0.965$. The cobalt-manganese alloys do not show the γ-phase, but an alloy with 11.5 per cent. of cobalt quenched from 1100° gave evidence of the presence of γ- and β-manganese lines. E. Oehman's observations on the alloy with iron are discussed in connection with the iron-manganese alloys. G. Hägg also found a high temp., face-centred, tetragonal phase in his study of the manganese-nitrogen alloys. E. Persson and E. Oehman added that since β-manganese is brittle at room temp., γ-manganese is malleable, hence the transition should be accompanied by a sudden change in physical properties. In agreement with this inference, they found that both α- and β-manganese are much less brittle at 600° than at room temp., and at 900° C. the β-manganese is in fact malleable, although very hard. At 1160° the hardness is still considerable, while at 1200° the metal has become extremely soft. An alloy with 21.8 per cent. of iron is hard at 1100°, but very soft at 1150° C., while an alloy with 8 per cent. of copper is quite soft at 980°. There seems to be no doubt, therefore, that the transition point $\gamma\rightleftharpoons\beta$ is 1191°. The point 1024°, on the other hand, does not seem to be accompanied by any change in crystal structure. It may be mentioned that the higher point in M. L. V. Gayler's curves is more pronounced than the lower. In no case has the γ-manganese phase been found in equilibrium with the face-centred cubic one (copper, γ-iron, etc.). This does not prove that the

cubic lattice continuously changes into the tetragonal, but if a two-phase range exists, it must certainly be very narrow. S. Sekito found for α-manganese that the cubic crystals have a lattice with $a=8\cdot904$ A., 58 atoms per unit cell and a range of stability up to 800° ; for β-manganese, a cubic lattice with $a=6\cdot288$ A., 20 atoms per unit cell, and a range of stability from about 800° to about 1100° ; and for γ-manganese a tetragonal cell with $a=3\cdot776$ A., and $a:c=1:0\cdot940$, and a range of stability over 1100°. When copper forms a solid soln. with manganese, the axial ratio $c:a$ increases with the copper content until it becomes unity. W. Schmidt obtained evidence of another form, ε-manganese, with a close-packed, hexagonal lattice in iron alloys with 16 to 20 per cent. manganese. E. Oehman's observations on the range of stability of this phase are discussed in connection with the iron-manganese alloys, and he found for the lattice $a=2\cdot541$ A., $c=4\cdot106$ A., and $a:c=1:1\cdot616$. It is not stable below 500°.

The **specific gravity** of manganese naturally depends on its degree of purity, so that of the early workers, J. G. Gahn gave 7·05 ; T. Bergman, and P. J. Hjelm, 7·0 ; J. F. John, 8·013 ; R. Böttger, 8·03 ; H. Davy, 6·85 ; C. Brunner, 7·138 to 7·207 ; C. Bullock, 7·231 (fused) ; J. E. Loughlin, 7·84 to 7·99 ; D. Zereteli, 7·7 ; O. Prelinger, 7·4212 at 4° (powder) ; E. Glatzel, 7·376 at 22°/4° (fused) ; E. Kuh, 7·241 at 0°, and 7·232 at 20° (fused) ; and R. Frilley, 7·40 at 15°/4° (fused). A. N. Campbell gave 7·034 to 7·080 for the sp. gr. of nodules of the electrolytic metal, and added that these are minimum values, because pores filled with hydrogen or vacuous may be present. He also discussed the at. vol. A. Westgren and G. Phragmén calculated from the X-radiograms, 7·21 for sp. gr. of the fused α-metal ; 7·29 for the β-metal ; and 7·21 for the γ-metal ; while A. J. Bradley gave 7·21 for the electrolytic or γ-metal. According to Y. Matsuyama, manganese contracts 1·69 per cent. of its vol. on solidification. K. Honda and co-workers gave −4·50 per cent. for the change in vol., $\delta v/v$, on melting manganese, and for manganese with 1 per cent. of carbon, −1·60 per cent. M. N. Saha calculated the **atomic radius** to be $0\cdot98\times10^{-8}$ cm. ; G. Natta, 0·90 A. ; M. L. Huggins, 1·39 A. (bivalent) ; and W. L. Bragg, 1·47 A., and for electronegative manganese 1·17 A. A. Ferrari gave 2·50 A. for the diameter of quadrivalent $Mn^{····}$-ions, and 2·95 A. for bivalent $Mn^{··}$-ions. G. Natta and L. Passerini found that if the at. radius of oxygen is 1·32 A., that of manganese is 0·89 A. H. G. Grimm, A. Kapustinsky, V. M. Goldschmidt, L. Pauling, E. T. Wherry, A. M. Berkenheim, J. C. Slater, W. F. de Jong and H. W. V. Willems, E. Rabinowitsch and E. Thilo, and E. Herlinger studied this subject. It follows from this work that for septivalent manganese atoms, the effective at. radius is 0·46 A. ; for quadrivalent atoms, 0·50 to 0·52 A. ; for bivalent atoms, 0·80 to 0·91 A. ; and for neutral manganese atoms, 1·17 to 1·54 A. A. Kapustinsky studied the effect of hydration or solvation. E. Persson obtained for the at. vol. of α-Mn, $12\cdot13$ A.[3] ; of β-Mn, $12\cdot50$ A.[3] ; and of γ-Mn, $12\cdot58$ A.[3]. A. N. Campbell, W. Biltz and K. Meisel, and J. J. Saslawsky discussed the at. vol. ; and P. Vinassa, the mol. number. W. Biltz and K. Meisel gave 7·26 for the at. vol. at absolute zero.

As indicated above, M. L. V. Gayler, and others have noted the brittleness and **hardness** of the metal ; J. B. Dumas noted that the manganese he tried scratched steel. J. R. Rydberg gave 6 for the scratching hardness on Mohs' scale. T. Turner said that the hardness of manganese is 1456 when that of iron is 1375, that of copper is 1360, and that of the diamond, 3010. W. C. Roberts-Austen found the **tensile strength** to be 7·99 tons per sq. in., and the elongation 29·7 per cent. on a 3-in. test-piece. W. Widder found that the elastic modulus is approximately a linear function of the temp. $E=E_{20}\{1-0\cdot001587(\theta-20)\}$. T. W. Richards gave $0\cdot82\times10^{-6}$ for the **compressibility** of the metal in sq. cm. per kilogram between 100 and 510 kgrms. per sq. cm. P. W. Bridgman measured this constant and found at 30° $-\delta v/v_0=7\cdot91\times10^{-7}p-5\cdot3\times10^{-12}p^2$; and at 75°, $-\delta v/v_0=8\cdot08\times10^{-7}p-4\cdot8\times10^{-12}p^2$. These and T. W. Richards' value are said to be out of line with the neighbours of manganese in the periodic table, whereas a value $5\cdot6\times10^{-7}$ would make a better

fit. G. A. Tomlinson discussed the **cohesive forces**. F. C. Kelley discussed the **diffusion** of manganese in iron; and J. H. Hildebrand and co-workers, the **internal pressure**.

According to J. Disch,[2] the coeff. of **thermal expansion** of manganese is $0 \cdot 0_4 228$ between 0° and 100°; and $0 \cdot 0_4 159$ between $-190°$ and 0°; while E. Kuh gave $0 \cdot 0_4 20697$ between 20° and 85°. W. Widder gave $\beta = 0 \cdot 0000261$ at 20° and $0 \cdot 0000213$ at $-190°$. H. V. Regnault gave $0 \cdot 1332$ for the **specific heat** between 13° and 97°; and H. Kopp, $0 \cdot 127$. J. Dewar gave $0 \cdot 0229$ between $-253°$ and $-196°$; T. W. Richards and F. G. Jackson, $0 \cdot 0931$ between $-188°$ and 20°; T. Estreicher and M. Staniewsky, $0 \cdot 0945$ between $-188°$ and 13°, and $0 \cdot 0945$ between $-79 \cdot 2°$ and 15°; and N. Stücker gave $0 \cdot 1211$ between 20° and 100°, and $0 \cdot 1673$ between 20° and 550°. N. Stücker gave for the true sp. ht., c:

	60°	125°	225°	325°	425°	525°
c	$0 \cdot 12109$	$0 \cdot 12790$	$0 \cdot 16644$	$0 \cdot 17830$	$0 \cdot 17257$	$0 \cdot 24774$

$c = 0 \cdot 1279 + 0 \cdot 000181(\theta - 125) + 0 \cdot 0_5 20(\theta - 125)^2$, between 125° and 225°; $c = 0 \cdot 1279 + 0 \cdot 000519(\theta - 125) - 0 \cdot 0_5 13(\theta - 125)^2$, between 125° and 325°; $c = 0 \cdot 1783 - 0 \cdot 000121(\theta - 325) + 0 \cdot 0_6 6(\theta - 325)^2$, between 325° and 425°; $c = 0 \cdot 1783 - 0 \cdot 000462 - (\theta - 325) + 0 \cdot 0_5 40(\theta - 325)^2$, between 325° and 525°; $c = 0 \cdot 1279 + 0 \cdot 000204 - (\theta - 125) + 0 \cdot 0_6 2(\theta - 125)^2$, between 125° and 525°; and $c = 0 \cdot 1211 + 0 \cdot 000105(\theta - 60)$, between 60° and 125°. R. Lämmel gave $0 \cdot 0979$ at $-100°$; $0 \cdot 1072$ at 0°; $0 \cdot 1309$ at 300°; and $0 \cdot 1652$ at 500°; or $c = 0 \cdot 10722 + 0 \cdot 0_4 78012\theta - 0 \cdot 0_6 11085\theta^2 + 0 \cdot 0_9 38178\theta^3$. The corresponding **atomic heats** are $1 \cdot 26$ at $-253°$ to $-196°$; $5 \cdot 89$ at 0°; $7 \cdot 19$ at 300°; and $9 \cdot 07$ at 500°. E. Kuh gave $0 \cdot 12130$ for the sp. ht. at $98 \cdot 5°$ and $6 \cdot 68$ for the at. ht. of fused manganese. J. Maydel discussed some relations of the sp. ht. and gave $0 \cdot 11542$ and $6 \cdot 36$, respectively, for the sp. and at. ht. of the powdered metal. He also represented the at. ht. by $A = 8 \cdot 734 - 938 \cdot 9(\theta + 352)^{-1}$.

H. St. C. Deville observed that the **melting point** of manganese is above that of iron. P. A. van der Weyde, and T. Carnelley gave 1900° for the m.p.; K. Hiege, 1260°; F. Heinrich, 1250°; W. C. Heraeus, 1245°; M. Levin, and G. Tammann, 1247°; W. R. Mott, 1207°; F. Wüst and co-workers, 1210°; E. Tiede and E. Birnbräuer, 1290°; R. S. Williams, 1228° for $98 \cdot 7$ per cent. Mn; R. Sahmen, 1214° for $99 \cdot 3$ per cent. Mn; A. D. Dourdine, 1235°; G. Hindrichs, 1207° for 98 per cent. Mn; S. F. Schemtschuschny and N. N. Effimoff, 1245° for $99 \cdot 4$ per cent. Mn; N. Baar, 1209° for $98 \cdot 78$ per cent. Mn; G. Arrivant, 1235° for manganese with less than $0 \cdot 5$ per cent. Fe; E. Newbery and J. N. Pring, $1230° \pm 5°$; J. Johnston, 1225°; S. Umino, 1221°; G. K. Burgess and R. G. Waltenberg, 1255° for 97 to 98 per cent. Mn; F. Doerinckel, 1244° for $99 \cdot 4$ per cent. Mn; R. Hadfield, 1240° in vacuo for $97 \cdot 47$ and $98 \cdot 40$ per cent. Mn; O. Ruff and E. Gersten, 1243° for $98 \cdot 7$ per cent. Mn; and M. L. V. Gayler, 1245° on the heating curve, and 1242° on the cooling curve of $99 \cdot 99$ per cent. Mn. W. Widder discussed the relation between the m.p. and the elastic constants; W. Crossley, between the at. vol. and the m.p.; and T. Carnelley, between the m.p. and the coeff. of thermal expansion. Z. Herrmann estimated the energy of manganese at the m.p. The ready **volatilization** of manganese was noted by S. Jordan, E. Kuh, W. N. Hartley, R. Lorenz and F. Heusler, and H. Moissan, and this even at temp. just above its m.p. H. C. Greenwood gave 1900° for the **boiling point** of manganese at 760 mm.; O. Ruff and W. Bormann, 1510° at 30 mm. press.; W. R. Mott, 2400° (calculated); while R. W. Millar gave 1900° at 760 mm.; 1820° at 500 mm.; 1555° at 100 mm.; 1465° at 50 mm.; 1285° at 10 mm.; 1080° at 1 mm.; and 925° at $0 \cdot 1$ mm. press. O. Ruff and co-workers gave 1526° for the beginning of the boiling of manganese saturated with carbon. R. W. Millar represented the **vapour pressure**, p mm., by $\log p = 2 \cdot 963 \log T - 12700 T^{-1} + 18 \cdot 621$; and J. Johnston, $\log p = -12300 T^{-1} + 8 \cdot 55$, and

p mm.	10^{-3}	10^{-2}	10^{-1}	1	10	50	100	760
B.p.	790°	890°	1020°	1170°	1360°	1530°	1610°	1900°

F. Wüst and co-workers, and W. Herz gave for the **heat of fusion** at 1210°, 36·7 cals. per gram, or 2·01 Cals. per gram atom ; E. Kordes gave 1·36 units for the entropy change on melting. S. Umino gave 64·8 cals. per gram ; and for the **heat of transformation** at 835°, 2·88 cals. per gram ; and at 1044°, 4·53 cals. per gram. A. Guntz found that the **heat of oxidation** of the pyrophoric metal $(Mn,O)=90·6$ Cals. ; and that of the fused metal, $(Mn,O)=94·8$ Cals.; hence the **heat of formation** of the more chemically active pyrophoric metal from the metal which has been fused is 3·8 Cals. H. von Jüptner gave $2Mn+O_2=2MnO+181·9$ Cals. ; and $Mn+O_2=MnO_2+125·3$ Cals. J. Thomsen found that the **heat of solution** of the fused metal in hydrochloric acid is 49·7 Cals. F. Wüst and co-workers gave 24·14 cals. for the heat of transformation of manganese into an allotropic form between 1070° and 1130°. G. N. Lewis and co-workers found the **entropy** of manganese to be 7·3 Cals. per degree at 25° and one atm. press. ; W. Herz, 11·00 ; and E. D. Eastman calculated 6·9 to 8·2 Cals. per degree by two different methods. B. Bruzs gave 20·2 for the entropy at the m.p., and 7·3 at 25°. R. D. Kleeman discussed the internal and free energy of manganese ; and W. Herz, the entropy.

H. von Wartenberg [3] gave $\mu=2·49$ for the **index of refraction** of manganese for the wave-length $\lambda=5790$; $k=3·89$ for the **index of absorption ;** and $R=64$ per cent. for the **reflecting power ;** J. T. Littleton gave for $\lambda=5893$, $\mu=2·41$, $k=3·88$, and $R=64·0$; while V. Fréedericksz gave :

λ	.	2570	3250	3600	4140	4680	5320	5880	6680
μ	.	0·661	1·005	1·159	1·390	1·653	1·846	2·246	2·619
k	.	1·186	1·758	2·078	2·495	2·833	3·267	3·753	4·050
R	.	36·5	42·9	48·3	53·4	56·1	60·4	63·5	64·5

G. Pfestorf gave :

λ	.	578	546	436	406	366	313	281	254	
μ	.	1·88	1·83	1·38	1·30	1·12	1·05	0·90	0·83	
k	.	1·85	1·73	1·92	1·90	2·00	2·03	2·04	2·02	
R	.	55·3	59·5	56·5	54·3	52·8	52·1	48·3	46·0	per cent.

J. H. Gladstone found the **molecular refraction** of manganese in its salts to be 0·222 ; and in the permanganates, 0·476 ; W. J. Pope gave 14·04 for the atomic refraction of manganese in manganous salts ; and J. H. Gladstone, 11·5. A. E. H. Tutton discussed this subject.

According to J. B. Nathanson, the reflecting power of manganese, distilled in vacuo, is from 61·6 to 63·5 per cent. for wave-lengths 4600 A. to 6800 A. The values at the blue end of the spectrum are greater and those at the red end are less than those obtained for manganese prepared in other ways.

W. Biltz [4] discussed the colour of manganese compounds. A colourless gas flame is coloured green by manganous chloride. W. A. Miller found green bands in the spectrum of manganous chloride in the alcohol flame, but he thought that the result was due to the chlorine, because other chlorides gave a green flame.
FIGS. 7 and 8.—The Flame and Spark Spectra of Manganese.

L. de Boisbaudran compared the result with the green flame of boric acid. According to J. Formanek, manganous chloride gives a **flame spectrum** which quickly vanishes as the manganese is oxidized. The flame spectrum, Fig. 7, consists of orange-yellow bands 6205 and 6179 ; a narrow yellow band 5848 ; a yellowish-green band $\alpha=5592$; and green bands $\beta=5424$, 5392, and 5360 ; $\gamma=5320$, 5193,

and 5158 ; and δ=5052, 5014, and 4984. These bands are produced when a large proportion of manganous chloride is present in the flame ; with a small quantity of the salt only the α, β, and γ bands are produced. Other manganese salts do not give this spectrum. H. Casaretto examined the band spectrum of manganous chloride in the oxy-coal-gas blowpipe flame ; and R. Mecke, the band spectrum of manganous oxide. The flame spectrum of manganese was examined by W. A. Miller, R. T. Simmler, R. Böttger, M. A. Catalan, A. Mitscherlich, J. Müller, A. R. Leeds, L. de Boisbaudran, A. Gouy, J. N. Lockyer, W. N. Hartley, O. Vogel, C. de Watteville, A. Hagenbach and H. Konen, H. Auerbach, J. Plücker and J. W. Hittorf, and E. Diacon. The spectrum in the oxyhydrogen or coal-gas flame was examined by W. N. Hartley, W. N. Hartley and H. W. Moss, and H. Casaretto. One way of controlling the bessemer steel process is to watch for the vanishing of the manganese bands from the flame spectrum ; it is then assumed that the decarbonization of the iron is complete. The spectrum of the bessemer flame has been examined by W. M. Watts, W. N. Hartley, and C. J. Lundström. The more important lines of the **spark spectrum** of a manganous chloride soln. are : an orange-yellow line 6017, β, Fig. 8 ; the green lines 5420, 5413-δ, 5377-ζ, and 5341-γ ; the four blue lines α, 4824, 4784, 4766, and 4754 ; and the indigo-blue line 4462-ϵ. There are numerous other lines of minor importance in the recognition of the manganese spark spectrum. Observations were made by W. A. Miller, W. Huggins, W. F. Meggers and co-workers, F. Exner and E. Haschek, W. Beckmann, R. Thalén, W. N. Hartley, W. N. Hartley and H. W. Moss, E. O. Hulburt, W. Kraemer, A. W. Smith and M. Muskat, J. N. Lockyer, K. Burns, M. A. Catalan, S. P. de Rubies, E. Back, G. Ciamician, J. Parry and A. E. Tucker, F. McClean, A. de Gramont, E. Demarçay, W. E. Adeney, O. Lohse, C. Fritsch, A. Hagenbach and H. Konen, J. H. Pollok and A. G. G. Leonard, L. Janicki, J. M. Eder and E. Valenta, and C. M. Kilby. According to W. N. Hartley, 0·0001 per cent. of manganese can be detected in a soln. by the spectral lines. The **arc spectrum** was examined by J. R. Capron, A. Sellerio, R. Thalén, F. Exner and E. Haschek, R. Frerichs, S. P. de Rubies and J. Dorronsoro, S. P. de Rubies, C. C. Kiess and W. F. Meggers, W. F. Meggers and co-workers, S. Wirminghaus, A. S. King, G. S. Monk, K. Burns, J. C. McLennan and A. B. McLay, E. Back, B. Hasselberg, R. E. Loving, A. Hagenbach and H. Konen, M. A. Catalan, A. Hornli, W. J. Humphreys, H. Fuchs, and C. M. Kilby. The spectrum of the dust in explosions of gases was examined by G. D. Liveing and J. Dewar ; the **absorption spectrum** of the vapour, by J. N. Lockyer and W. C. Roberts-Austen, R. V. Zumstein, G. A. Hemsalech, A. S. King, R. G. Loyarte and A. T. Williams, J. Fridrichson, J. C. McLennan and E. Cohen. A. W. Smith and M. Muskat, J. Parry, W. Grotrian, and H. Geisler ; the **ultra-violet spectrum,** by W. A. Miller, R. J. Lang, L. and E. Bloch, S. Wirminghaus, J. Schönn, A. Cornu, and F. Exner and E. Haschek ; and the **ultra-red spectrum,** by C. C. Kiess and W. F. Meggers, and H. M. Randall and E. F. Barker. The *anomalous dispersion* was examined by L. Puccianti, and H. Geisler ; the *self-induction,* by G. A. Hemsalech, and C. M. Kilby ; the *enhanced lines,* by M. Kimura and G. Nakamura ; the *ultimate rays,* by A. T. Williams ; the effect of *pressure,* by W. J. Humphreys, and G. S. Monk ; and the effect of a *magnetic field*—the **Zeeman effect**—by A. A. Michelson, E. Back, J. E. Purvis, O. Lüttwig, J. H. van Vleck and A. Frank, W. C. van Geel ; J. Parry discussed the periodic law and spectra ; and H. Kayser and C. Runge, K. Bechert and M. A. Catalan, H. N. Russell, A. Sommerfeld, S. Goudsmit, D. R. Hartree, R. A. Sawyer, J. C. McLennan and A. B. McLay, G. Wentzel, F. Croze, S. Kawata, C. C. Kiess and O. Laporte, W. F. Meggers and co-workers, O. S. Duffendack and J. G. Black, R. Frerichs, H. E. White, R. C. Gibbs and H. E. White, H. E. White and R. Ritschl, E. Paulson, A. E. Ruark and R. L. Chenault, and P. G. Nutting, the structure of the lines, and the **series spectra.** M. A. Catalan said that the flame, arc, and spark spectra of manganese, like those of other elements, are formed by two classes of lines, some belonging to the neutral atom, and some to

the ionized atom, Mn$^+$. There are triplet series and combination lines in the spectrum of the neutral atom. The lines of ionized manganese, enhanced lines, also form triplets ; there is a system of sharp, diffuse, and principal triplets, and another system of narrower triplets corresponding with the single line systems

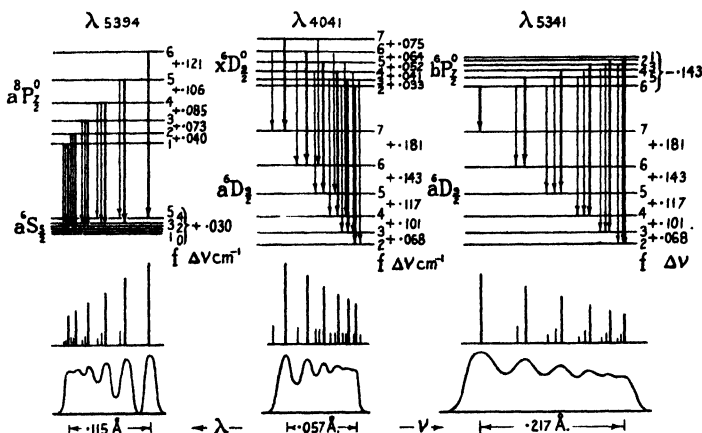

FIG. 9.—Hyperfine Structure of the Spectrum of Manganese.

in the alkaline earths, as in the case of the neutral atom. Each spectral line in manganese is really a tiny multiplet. H. E. White and R. Ritschl represented the fine structure of the manganese lines 5394, and 4041 at liquid air temp., and 5341 from a vacuum furnace in Fig. 9, and the 4823, 4783, and 4754 lines at liquid air temp. in Fig. 10. The subject was discussed by R. S. Seward.

I. Lifschitz and E. Rosenbohm [5] examined the **absorption spectrum** of manganese salts. According to P. Lambert, the absorption spectrum of manganous chloride has an intense broad band between 5130 and 5575 ; a broad, less intense band between 4200 and 4425 ; and a group of six narrow bands 4102·5 to 4122·5, 4052·5 to 4080, 4020 to 4032·5, 4000 to 4010, 3962·5 to 3977·5, and 3945 to 3957·5. According to J. Formanek, a neutral soln. of manganous chloride reacts with tincture of alkanna without changing the colour of the liquid, but the absorption spectrum is displaced to the left, and a band appears at 6145. If aq. ammonia is added—not enough to produce a turbidity—the liquid becomes blue,

FIG. 10.—Hyperfine Structure of the Octet System of the Manganese Spectrum.

and the absorption spectrum shows bands at 6171, 5707 and 5303. The presence of iron or chromium interferes with the results. W. A. Miller, and E. Luck observed the absorption spectrum of manganic chloride. W. Friederichs gave 5274, 5212, 5070, 5002, 4882, 4829, 4708, 4663, 4543, and 4390. J. M. Hiebendaal found a feeble

band at 5890 to 5440 with a soln. of manganous phosphate in water. Observations on the manganous salts were also made by H. W. Vogel, F. Hoppe-Seyler, J. Moir, C. J. W. Grieveson, N. von Klobukoff, C. Kubierschky, and J. M. Hiebendaal. W. Jäschke and J. Meyer examined the absorption spectra of potassium manganate and permanganate, of manganese tetrachloride, of manganic chloride, sulphate, and phosphate, and of manganous chloride and sulphate. The absorption spectra of all the compounds show great similarity, particularly in respect of the band in the red; this band is very persistent, and only disappears with the very dilute soln. of permanganate and manganous chloride. The central band appears, however, to be influenced by the valency, in the sense that it moves towards the red end of the spectrum with increasing valency. The violet end of the spectrum is most sensitive to changes in valency, but they were unable to make any measurements in that region or in the ultra-violet portion of the spectrum. The absorption spectrum of the permanganates can be recognized in soln. diluted 1 : 250,000. J. Formanek observed eight bands at 5710, 5473, 5256, 5054, 4870, 4707, 4544, and 4395—Fig. 11. L. de Boisbaudran observed bands at 5703, 5465, 5246, 5045, 4861, 4694, and 4543. A. Hagenbach and R. Percy's measurements gave 4388, 4537, 4695, 4866, 5050, 5249, 5461, and 5695. The bands are so related that there is a constant difference between the oscillation frequencies of successive members of the group. J. Formanek's broad band at 6370 can be resolved into the four bands at 5949, 6264, 6528, and 6862, so that these form a continuous series with the other eight bands. E. Adinolfi observed that the absorption spectrum is not influenced by the extent to which the salt is ionized in soln. Observations were also made by H. Kayser, T. R. Simmler, J. Müller, J. H. Gladstone, F. Hoppe-Seyler, J. Moir, A. Hantzsch and R. H. Clark, J. E. Purvis, T. R. Merton, W. Ostwald, V. R. von Kurelec, C. J. W. Grieveson, E. Adinolfi, H. Gombos, G. G. Stokes, H. Bremer, C. Pulfrich, H. Morton and H. C. Bolton, C. Christensen,

FIG. 11.—Absorption Spectrum of Potassium Permanganate Solutions.

K. Stöckl, W. N. Hartley, J. M. Hiebendaal, and K. Vierordt. J. L. Soret observed a band in the ultra-violet between 3900 and 2750. H. Bremer found that the bands are displaced about 50 A. towards the red as the temp. rises from 20° to 80°, and H. Morton and H. C. Bolton, and W. N. Hartley also observed a displacement of the bands with a rise of temp., but J. M. Hiebendaal observed that temp. has no influence on the position of the bands. K. Stöckl gave for conc. soln. 5645, 5410, 5225, 5065, and 4875; and for dil. soln. 5655, 5465, 5265, 5050, and 4890. H. W. Vogel found that the spectrum of the solid differs from that of the soln. by a stronger absorption between the bands. J. Holluta examined the absorption spectrum of the manganates, and the manganito manganates. G. B. Rizzo found the spectrum of manganese-tinted glass showed bands at 6740, 6560, 6380, 6030, 5900, 5830, and 5540 at 15°; at 6860, 6620, 6460, 6040, 5920, 5840, and 5540 at 300°; and 6660, 6500, 6050, 5930, 5850, and 5540. V. R. von Kurelec measured the absorption bands of potassium permanganate dissolved in various solvents. E. Viterbi studied the ultra-violet absorption spectrum of potassium permanganate soln.; C. L. Cross, the spectrum of manganese in glass; and K. Schlossmacher, the spectrum of manganese in spinels.

J. Fridrichson [6] examined the **resonance spectrum** of manganese vapour; and L. de Boisbaudran, the **fluorescence spectrum** of manganese compounds in vacuo, under the influence of the electrical discharge. Many manganese compounds do not fluoresce after calcination, but they impart fluorescing properties to non-fluorescing substances. Thus, A. E. Becquerel, L. Bruninghaus, and V. Klatt and P. Lenard observed this with calcium sulphide (q.v.); J. R. Mourelo, with strontium sulphide; and H. Grüne, and the Chininfabrik Braunschweig, with zinc

sulphide. A. Dauvillier discussed the green fluorescence with manganese glass exposed to cathode rays; and A. Karl, the **triboluminescence** of the oxides and sulphides of manganese. According to T. Tanaka, manganese is the principal agent in the cathodoluminescence of artificial rubies, and spinel. W. G. Guy observed no **radioactivity** with the salts of manganese.

The absorption of the X-rays was studied by U. Andrewes and co-workers,[7] T. E. Aurén, and K. Chamberlain. The **X-ray spectrum** of manganese has lines in the K-series at a_1a, 2·09777; a_3a_4, 2·0879; $\beta_1\beta$, 1·902; and $\beta_2\gamma$, 1·892. The K-series was observed by V. Dolejsek, V. Dolejsek and K. Pestrecoff, V. Dolejsek and H. Filcakova, G. Kettmann, S. Björek, S. Eriksson, R. Thoroeus, S. Idei, S. Pastorello, G. B. Deodhar, K. Chamberlain, B. Kievit and G. A. Lindsay, H. Beuthe, T. Wetterblad, O. Stelling, G. Ortner, A. E. Lindh, H. R. Robinson, H. Walter, D. M. Bose, W. Duane and K. F. Hu, B. C. Mukherjee and B. B. Ray, W. Duane and H. Fricke, J. Schrör, E. Hjalmar, N. Seljakoff and co-workers, R. C. Gibbs and H. E. White, H. R. Robinson, D. Coster, M. Siegbahn, and N. Stensson; the L-series, by S. Björek, C. E. Howe, J. Schrör, H. Hirata, R. Thoroeus, R. Thoroeus and M. Siegbahn, B. C. Mukherjee and B. B. Ray, and M. J. Druyvesteyn; and the M-series, by U. Andrewes and co-workers, S. Björek, B. C. Mukherjee and B. B. Ray, and M. Levi. W. Duane and H. Fricke found the critical absorption wave-length is $1·8893 \times 10^{-8}$ cm. O. W. Richardson and F. S. Robertson, and F. C. Chalklin examined the emission of soft X-rays from manganese; L. P. Davis, the effect of oxidation on the emission of soft X-rays; and J. Fridrichson, the resonance radiation of manganese vapour.

D. R. Hartree[8] calculated 14·5 volts for the **ionizing potential;** M. A. Catalan, and J. G. Black and O. S. Duffendack gave 7·4 volts, and S. C. Biswas, 7·36 volts for the Mn-II spectrum; H. N. Russell also gave 7·40 volts for the first ionization potential, and 15·70 volts for the second one. A. C. Davies and F. Horton, F. C. Chalklin, and B. B. Ray and R. C. Mazumdar discussed the critical potentials for soft X-rays; A. Hantzsch and H. Carlsohn, the work of ionization; C. E. Eddy and co-workers, the analysis of manganese by means of the X-rays; D. M. Yost, the absorption of X-rays by manganous salts; R. W. James and G. W. Brindley, the scattering of X-rays; H. B. Wahlin, the emission of positive ions by the heated metal; R. H. Ghosh, the relation between the electronic structure and the ionizing potential; and H. N. Russell, the ionization in the solar atmosphere, and the ionizing potential. W. Herz gave $7·52 \times 10^{-12}$ for the **vibration frequency;** and J. E. P. Wagstaff, $7·5 \times 10^{-12}$. M. von Laue,[9] A. Goetz, and W. Espe studied the emission of electrons from the metal at a high temp. N. Piltschikoff observed that manganese emits positive Moser's rays. T. Pavolini, and O. W. Richardson and F. S. Robertson studied the photoelectric effect; U. Nakaya, the influence of adsorbed gas on the phenomenon; J. Fridrichson, the fluorescence of the vapour; and R. E. Nyswander and B. E. Cohn, the effect of manganese on the thermo-luminescence of glass. R. Robl observed no luminescence in ultra-violet light.

According to E. Kuh,[10] the **electrical resistance** of manganese is 0·00015298 ohm, and the **electrical conductivity,** 1225×10^4 mhos. A. Schulze gave 0·0000044 for the sp. resistance. W. Meissner and B. Voigt measured the resistance of two different samples of manganese down to $-271·8°$, and found for the ratio, r, of the resistance, R, at the given temp. to the resistance, R_0, at 0°, when for I, $R_0 = 5·161 \times 10^{-3}$ ohm at 0·16°, and for II, $6·486 \times 10^{-3}$ ohm:

	0·16	$-184·10°$	$-252·54°$	$-268·80°$	$-271·49°$	$-271 78°$
r for I . . 1	1	0·9776	1·0020	0·9765	0·9581	—
r for II . . 1	1	0·9695	1·0082	0·9900	—	0·9860

P. W. Bridgman studied the press. coeff. of the resistance of manganese, at 30°, up to 12,000 kgrms. per sq. cm., and obtained $\delta R/R_0 = -7·012 \times 10^{-6}p + 5·63 \times 10^{-11}p^2$. K. F. Herzfeld, and K. Höjendahl studied this subject from the point of view of the electron theory. P. Kapitza examined the effect of a magnetic field on the electrical conductivity of manganese.

J. B. Seth and co-workers studied the e.m.f. developed by manganese in contact with a rotating steel disc.   H. D. Royce and L. Kahlenberg [11] obtained values for the **electrode potential** of manganese against aq. soln. of manganous salts, in the absence of oxygen, by using a liquid or pasty manganese amalgam electrode which is continuously stirred.   The potential is independent of the concentration of the amalgam above 1·2 per cent. manganese.   Neglecting the liquid junction potential, and taking the potential of the normal calomel electrode as 0·560 volt, the potential of manganese against 0·5N-MnSO$_4$ is —1·452 volt ; N-MnSO$_4$, —1·449 volt ; N-MnCl$_2$, —1·436 volt ; and N-Mn(NO$_3$)$_2$, —1·232 volt. B. Neumann gave 0·815 volt for normal soln. of the sulphate ; 0·824 volt, chloride ; and 0·560 volt, nitrate ; V. Nejedly gave the e.m.f. E=1·510 volt, and $dE/d\theta$=0·0001510 volt for the temp. coeff. of the e.m.f. of manganese in a soln. of 0·001N-MnCl$_2$ and 0·1N-KCl.   H. Gerding gave for the normal electrode potential of manganese in aluminium sulphate E_H=—1·0 volt.   Observations on the potential of manganese were also made by T. J. Martin and A. J. Helfrecht, R. Lorenz and G. Hostelet, A. Thiel and W. Hammerschmidt, E. Newbery, and W. Muthmann and F. Fraunberger.   S. Kyropoulos detected a different potential in different parts of the same metal in soln. of potassium ferrocyanide.   O. Bauer observed that in a 1 per cent. soln. of sodium chloride, and with a normal calomel electrode, the potential was —1·305 volt at the start ; —1·200 volt after an hour ; and —1·120 volt after 120 hrs.   G. Grube and K. Huberich measured the oxidation potential of soln. of manganese sulphates in sulphuric acid—*vide* manganous sulphate.   A. N. Campbell found that the e.m.f. of the cell Mn | M-MnSO$_4$ | 3N-KCl | Hg$_2$Cl$_2$ (with 3N-KCl) | Hg is —0·797 volt at 12° ; and the potential of the half element Mn | 0·1M-MnSO$_4$ is —0·821 volt.   The **hydrogen over-voltage** with respect to N-Na$_2$SO$_4$ and 0·02-NaOH at 16° is :

| Over-voltage | . | 0·615 | 0·644 | 0·705 | 0·755 | 0·823 | 0·850 | 1·044 volt |
| Current density | . | 0·47 | 0·63 | 1·33 | 2·33 | 4·00 | 5·00 | 10·00 amp. per sq. dm. |

and with a current density of 3·33 amp. per sq. dm. :

| | 15·5° | 53·5° | 71° | 84° |
| Over-voltage | 0·801 | 0·622 | 0·507 | 0·393 volt |

For the normal potential of quadrivalent manganese ions in the presence of bivalent manganese ions, A. N. Campbell gave, on the hydrogen scale, 1·465 volts at 16°. According to W. Muthmann and F. Fraunberger, manganese is in many respects analogous to zinc, and does not show **passivity ;** on the other hand, E. Müller supposed that it does possess a very labile passivity, best shown when it is used as anode in a soln. of acidic sodium phosphate.   With a high enough current density —say 0·075 to 0·15 amp. per sq. cm.—it passes into a soln. as tervalent manganic phosphate and liberates oxygen.   The ammeter or the electrometer shows that pulsations occur ; with the minimum values for the e.m.f., hydrogen is evolved vigorously at the electrode, so that both hydrogen and oxygen appear.   This subject has been discussed by H. Kuessner, G. Grube and co-workers, and A. Günther-Schulze.   The **electrodeposition** of manganese has been discussed in connection with the preparation of manganese.   According to H. Kuessner, with a manganese anode in neutral solutions (of potassium chloride or sulphate), the metal dissolves, and both hydrogen and oxygen are evolved, the whole of the metal finally present in the soln. being bivalent.   Manganese itself dissolves, with evolution of hydrogen, but the rate is too slow to account for the quantities of hydrogen observed ; it is, therefore, thought probable that univalent manganese ions are formed, which react with the hydrogen ions in the soln. thus : 2Mn˙+2H˙=2Mn˙˙+H$_2$.   From 8 to 10 per cent. of the manganese dissolves in this way.   The oxygen is evolved when the potential of the manganese anode is more than 0·3 volt more negative than the normal hydrogen electrode, whilst hydroxyl ions could only be discharged directly if it were 1·62 volts more positive ; the oxygen is, therefore, a secondary

product. The potential measurements show further that the dissolution of manganese accompanied by evolution of oxygen at the anode and of hydrogen at the cathode is a process which takes place of its own accord; hence the gain of free energy due to the conversion of metallic manganese into ions cannot be less than the loss due to the decomposition of water. Following this out quantitatively, it appears that the manganese must dissolve primarily in the form of tervalent ions, which then react with hydroxyl ions thus : $2Mn^{...}+2OH'$ $==2Mn^{..}+H_2O+\frac{1}{2}O_2$. Increasing the alkalinity of the electrolyte leads to the formation of manganese ions of higher valency in increasing quantity. E. Müller found that when manganese is used as an anode in electrolysis, the manganese becomes passive in alkaline soln. of sodium sulphate or phosphate, but behaves normally in acidic and neutral soln. E. Müller also found that manganese dissolves in weakly acidic soln. of sodium phosphate as manganic phosphate at a high current density (7·5 to 15 amp. per sq. dm.), and oxygen is simultaneously evolved. The ammeter shows that pulsations are set up, and with the lowest value of the e.m.f., hydrogen is violently evolved at the electrode. This evolution again ceases, and the issuing gas contains oxygen and hydrogen, the presence of which may be shown by exploding the mixture. The passivity of manganese is so labile that, as anode, it falls back into the active condition. G. Grube and H. Metzger observed that with hot, conc. soda-lye, manganese passes into soln.—at low current densities as bivalent atoms ; at medium current densities as tervalent atoms ; and at still higher current densities as sexavalent atoms, which formed manganate. At room temp., however, or in dil. soda-lye, the manganese dissolves immediately in the septavalent condition. A. N. Campbell observed that the potential of manganese with no current flowing is -0.795 volt ; and with a current density of 0·7 to 7·0 amp. per sq. dm. it is -0.725. This gives 0·070 volt as the measure of the passivity. Hydrogen was freely evolved at the cathode, but no visible gas at the manganese anode. The soln. became somewhat cloudy, through precipitation of basic manganese sulphate in the neighbourhood of the cathode. Metallic manganese also was deposited on the cathode. There was no formation of permanganate. R. Saxon, and I. Slendyk made some observations on the subject. J. Chloupek found the normal potential of platinum for mixtures of equal proportions of tervalent and bivalent manganese phosphates in phosphoric acid soln. is 0·98 to 1·18 volts on the hydrogen scale. The instability of the soln. makes the results variable. B. N. Chuckubutti obtained Nobili's rings by the electrodeposition of manganese from a soln. of manganese sulphate on a brass plate.

A. Heydweiller gave 44 for the **ionic mobility** of manganese, $\frac{1}{2}Mn^{..}$, at 18°. E. Gapon and I. Z. Khaskes studied the hydration of bivalent manganese ions. Observations were also made by W. Althammer. W. Ostwald gave 240 cals. for the **heat of ionization** per valence. J. Thiele discussed the thermo-electric properties. H. Zahn and H. Schmidt found that the coeff. R of the Hall effect is -93×10^{-5}, and the coeff. Q of the thermo-magnetic effect is -15×10^{-6}. According to J. Brezina, with neutral or acidic soln. of manganous chloride, the electro-deposition of manganese at the dropping cathode proceeds reversibly, the deposition potential from a molar soln. being -1.326 volts, relative to the normal calomel electrode. The polarization curves permit the detection of manganous salts in soln. down to 10^{-6} mols per litre. The deposition potential becomes negative in the presence of ammonia owing to the formation of complex cations. W. Ogawa studied the activation of galena as a radio-detector by manganese salts. The simultaneous precipitation of manganese and zinc was discussed by O. C. Ralston. H. Nagaoka and T. Futagami discussed the spluttering of manganese by the disruptive discharge in a magnetic field; M. Haitinger, the intensity of the ultra-violet light from a manganese arc-light ; and C. E. Mendenhall and L. R. Ingersoll found that small globules of metal on Nernst's glower move against the current. K. Meyer and A. Günther-Schulze studied the cathodic spluttering of manganese.

There has been some discussion as to whether manganese is paramagnetic or

not. The paramagnetism has been attributed to the presence of its oxides or of metallic iron as impurities. M. Faraday, and E. Seckelson found specimens of electrolytic manganese to be ferromagnetic ; and P. Weiss and H. K. Onnes obtained a sample of manganese, as a grey powder, by electrolyzing a soln. of the purified chloride, with a mercury cathode, and subsequently distilling off the mercury ; when the powder was compressed in the form of a rod, it was paramagnetic. The powder was fused in a magnesia boat, and the external film of oxide was turned off with a diamond-pointed tool. The rod was ferromagnetic. Fig. 12 represents the hysteresis curve—*vide* iron. P. Kapitza studied the magnetic properties of manganese. The maximum value of the sp. magnetization is a hundred times weaker than that of iron, and the coercive force is

FIG. 12.—Cyclic Magnetization of Manganese—Hysteresis Loop.

670 gauss—that is, ten times as strong as that of steel used for making good permanent magnets. The rod was strongly attracted between the poles of a magnet, and placed itself perpendicular to the field. Hence, manganese of the same degree of purity can occur in two states—paramagnetic and ferromagnetic. E. Wiedemann [12] found that the **atomic magnetism** of manganese in potassium manganic oxalate is 70·58 and in the fluoride 43·25 when that of iron in $FeCl_3$ is 100. P. Collet gave $56·5 \times 10^{-6}$ unit for the manganese in potassium permanganate (q.v.). O. Liebknecht and A. P. Wills made some

observations on the paramagnetism of manganese salts. K. Honda and T. Sone gave $10·1 \times 10^{-6}$ unit for the **magnetic susceptibility** of manganese at 18°, and 20×10^{-6} unit at 1000°. M. Owen gave $8·39 \times 10^{-6}$ mass unit ; E. Kuh, 2130×10^{-6} and 1080×10^{-6} ; and T. Ishiwara, $9·66 \times 10^{-6}$ mass unit ; while K. Ihde gave 80×10^{-6} vol. unit. K. Honda and T. Sone observed a discontinuity in the curve for the magnetic susceptibility of manganese at 1040° ; and Y. Shimizu found that the magnetic susceptibility of 99·9 per cent. manganese at room temp. is $7·55 \times 10^{-6}$ mass unit, and at higher temp. the value changes as indicated in Fig. 13. There is an abrupt increase at 810° corresponding with the allotropic $\alpha \rightarrow \beta$ transformation ; and one at 1100° corresponding with the $\beta \rightarrow \gamma$ transformation. According to R. Hadfield and co-workers, powdered manganese has a paramagnetic susceptibility of $11·0 \times 10^{-6}$ mass unit ; cast manganese is ferromagnetic, but after repeated heating to redness and washing with hydrochloric acid, the mass susceptibility gradually fell from 2000×10^{-6}, approaching the value for powdered manganese. The ferromagnetic properties were inferred to be due to occluded hydrogen. Manganese steels gave variable and large values, which were greatly reduced, after washing with hydrochloric acid to remove surface ferriferous impurities, to the

FIG. 13.—The Magnetic Susceptibility of Manganese at Different Temperatures.

order of 75 to 100×10^{-6}. W. Lepke found that for a field strength of H kilogauss, the mass susceptibilities $\times 10^6$ of massive and powdered manganese are :

H	.	.	0·8	1·0	2·1	7·0	10·0	16·0	18·9
Mass	.	.	9·4	10·3	10·5	9·9	9·8	9·5	9·4
Powd.	.	—		10·7	11·6	10·3	10·2	9·7	9·6

R. H. Weber, A. Duperier, J. H. van Vleck and A. Frank, B. Cabrera, and K. Ihde made observations on this subject—*vide infra*, cupromanganese. M. Faraday suggested that possibly manganese at ordinary temp. is above its critical point, but P. Weiss and H. K. Onnes observed no indication of a ferromagnetic state at −259°.

C. E. Guillaume's suggestion that Heusler's alloys owe this magnetic state to the effect of aluminium in raising the temp. of magnetic transformation has no experimental support. P. Weiss and H. K. Onnes found that the magnetic induction, B, and intensity, H, curve showed the large coercive force of 670 C.G.S. units. Even at $H=12,000$ the specimen was not saturated. This agrees with the assumption that this element possesses a ferromagnetic property. The saturation intensity, l, deduced from the manganese alloys is $l_s=2300$, whereas that for iron is 1700. H. Freese, and I. Tamm studied the magnetizability of thin films of manganese ; E. H. Williams, the relation of magnetism and valency ; and J. C. Thomson, the relation between magnetism and thermoelectric force. S. S. Bhatnagar and co-workers found that manganese salts lose their paramagnetism and become diamagnetic when adsorbed on charcoal. The subject was studied by D. M. Bose, and L. Sambi and L. Szegö ; P. Weiss, C. Sadron, and E. C. Stoner discussed the magnetic moment of manganese ; and P. Weiss, A. Chatillon, and B. Cabrera, the structure of the magnetic molecules ; and J. C. Slater, the place of manganese in the theory of magnetism—vide iron.

§ 5. The Chemical Properties of Manganese

W. Guertler [1] discussed the chemical affinity of manganese. F. Fischer and F. Schröter observed no reaction when manganese is sparked beneath liquid **argon**. L. Troost and P. Hautefeuille made observations on the absorption of gases by

molten manganese ; they found that the solubility of **hydrogen** in molten cast-iron is increased in the presence of manganese, and that manganiferous iron retains more hydrogen than ordinary cast-iron. A. J. Allmand and A. N. Campbell found that electrodeposited mangan ese contained 12·6 c.c. of hydrogen, at n.p. θ, per gram, or 89 c.c. of hydrogen per c.c. of metal. The manganese suffers no perceptible change when the occluded gas is withdrawn ; the metal is as brittle as before. R. Lorenz and F. Heusler observed no evidence of the formation of a *manganese hydride* when the metal is heated in hydrogen. G. F. Hüttig discussed this subject. G. Hägg studied the mol. vol.

According to H. Davy,[2] when manganese is heated strongly in **oxygen,** it burns with great brilliancy, throwing off brilliant sparks ; and A. N. Campbell added that owing to the volatility of the manganese, the oxide which is formed cannot be weighed. According to G. Tammann and N. I. Nikitin, the powder is not pyrophoric if over 50 per cent. manganous oxide is present, even if the metal is reduced at a low temp. The observation of G. C. Stone that permanganic anhydride can be formed by the combustion of manganese in air has not been confirmed. J. Bachmann found that when manganese is heated in **air,** it rapidly forms the tritetroxide, without incandescence. H. Davy said that manganese is immediately tarnished in air, becoming grey, brown, and at last black. Ordinary, impure manganese obtained by the carbon reduction process was found by J. J. Berzelius to be readily oxidized at room temp. N. G. Sefström observed that if 6 to 7 per cent. of silicon is present, the regulus can be heated to redness without oxidation, and it also resists attack by aqua regia. J. J. Berzelius imagined that the presence of silicon is not a sufficient explanation of the phenomenon, because platinum alloyed with silicon is attacked by aqua regia ; he said that the difference is due to the existence of the metal in two *allotropic forms* : α-manganese which is active chemically, and β-manganese, inactive. This hypothesis has not been confirmed. H. Moissan found that the manganese formed by distilling mercury from the amalgam below 360° is pyrophoric ; but A. Guntz and J. Férée showed that the metal obtained by heating the amalgam at a red-heat is non-pyrophoric. H. Moissan found that the metal obtained by the electric arc furnace process behaves very much like iron in air. H. Goldschmidt observed that the metal obtained by the aluminothermite process can be kept indefinitely in air without oxidation. M. L. V. Gayler also found that the 99·99 per cent. manganese, obtained by distillation in vacuo, does not tarnish in air. On the other hand, R. Bunsen found that the metal he obtained by electrodeposition oxidizes in moist air as rapidly as potassium. The impure forms of manganese also decompose **water** at ordinary temp. with the evolution of hydrogen ; this was noticed by J. F. John, J. Bachmann, R. Bunsen, J. E. Loughlin, and H. St. C. Deville. J. Bachmann said that the hydrogen evolved has a fœtid odour—indicating impurities in the metal. H. V. Regnault said that finely-divided manganese kept under water at ordinary temp. slowly liberates hydrogen, but if heat be applied, even below 100°, the evolution of gas is rapid, and a yellowish-brown powder is formed which becomes dark brown on exposure to air. H. Moissan also observed that pyrophoric manganese decomposes water slowly in the cold, and rapidly at 100° ; and similar results were obtained by O. Prelinger. C. Brunner found that the metal contaminated with silicon is only attacked by water very slowly, a film of oxide being formed after some days' contact. A. N. Campbell observed that with powdered, electrolytic manganese in contact with water no gas was evolved over-night and the metal remained dead-black, but a freshly cut surface exposed to moist air soon tarnished by a phenomenon analogous to rusting ; the same manganese is slowly attacked by boiling water, forming bubbles of gas and a brown hydrated oxide. If the metal be heated in a current of steam, at the temp. of a bunsen flame, tiny bubbles of gas are formed, but the action is very slow. L. J. Thénard found that **hydrogen dioxide** is vigorously decomposed by manganese.

According to H. Moissan, massive manganese is attacked by **fluorine** only

superficially at ordinary temp., but the powdered metal furnishes a mixture of di-
and trifluorides and the rise of temp. is so great that the platinum boat containing
the metal was melted. H. Davy found that heated manganese takes fire in **chlorine**
and burns brilliantly. A. N. Campbell observed that the metal ignites in chlorine
at a red-heat, forming a light brown, highly crystalline powder, probably manganous
chloride, but combustion appears to be incomplete. Observations were also made
by H. Moissan, and J. B. Berthemot. C. J. Löwig found that when powdered
manganese is heated in **bromine,** manganous bromide is formed; while A. N. Camp-
bell observed that boiling bromine does not attack the metal, but bromine-water
was found by J. B. Berthemot to form manganous bromide. W. Engelhardt said
that colloidal manganese does not react with **iodine,** and R. Hanslian found that
boiling or freezing iodine has no perceptible action on manganese. J. F. John,
and C. Brunner observed that manganese readily dissolves in dil. **hydrochloric acid,**
with the evolution of hydrogen; A. N. Campbell obtained a similar result with the
electro-deposited metal.

K. Jellinek and J. Zakowsky, and W. Guertler discussed the affinity of manganese
for **sulphur.** According to O. Prelinger, sulphur unites directly with manganese at
a high enough temp., but at the temp. employed by A. N. Campbell no action occurs
when manganese is heated with an excess of sulphur; and, according to E. Beutel and
A. Kutzelnigg, surface films are produced by heating the metal in contact with the
sulphides of copper, silver, mercury, and lead. O. Bauer and H. Arndt found that
manganese is not attacked by sulphur or plastilin. E. H. Harvey found that man-
ganese is attacked by **sulphur monochloride** at room temp.; H. E. Patten observed
no attack, and similarly also with **thionyl chloride.** A. Guntz observed that pyro-
phoric manganese burns with a brilliant flame when heated in **sulphur dioxide :**
$3Mn+SO_2=MnS+2MnO+82\cdot4$ Cals.—no sulphite or sulphate is produced.
P. Schützenberger found that manganese reduces acid **sodium sulphite** to hypo-
sulphite. C. Brunner, and J. F. John observed that conc. **sulphuric acid** acts on
manganese very slowly; and O. Prelinger found that with non-pyrophoric man-
ganese, the action of the conc. acid is very slow, but with warm conc. acid, sulphur
dioxide is evolved; A. N. Campbell found that the reaction corresponds with the
equation : $Mn+2H_2SO_4=MnSO_4+2H_2O+SO_2$. R. H. Adie observed that gas is
evolved with conc. sulphuric acid and manganese at 120° to 155°, and no hydrogen
sulphide is formed. Dil. sulphuric acid was observed by J. F. John to dissolve
manganese rapidly; and, added A. N. Campbell, the reaction virtually ceases with
a dilution of $0\cdot005N$-H_2SO_4. J. Bachmann found that when the hydrogen produced
by the action of dil. sulphuric acid on manganese is exploded with an excess of
oxygen, a white, greasy substance is formed with the disagreeable odour of the gas—
possibly silica derived from impurities in the metal. E. Beutel and A. Kutzelnigg
found that manganese in a boiling soln. of **sodium thiosulphate** and lead acetate
acquires a sequence of colours from yellow to steel-blue, presumably owing to a
film of sulphide. M. G. Levi and co-workers found that manganese dissolves in
soln. of **ammonium and potassium persulphates**, forming violet soln.

W. C. Heraeus observed that when manganese prepared by the alumino-thermite
process is heated at 1210° to 1220° in a current of **nitrogen,** it burns, forming white
fumes of nitride; and S. Hilpert and co-workers, A. P. Lidoff, I. Zschukoff, G. Valensi,
L. Duparc and co-workers, R. Ochsenfield, and A. N. Campbell obtained a nitride in a
similar manner. O. Meyer observed that manganese is but slightly attacked by
titanium nitride at 1400°. G. Gore found that manganese is insoluble in liquid
ammonia. O. Prelinger, and L. Santi found that manganese is attacked by a soln.
of **ammonium chloride :** $Mn+4NH_4Cl=MnCl_2.2NH_4Cl+2NH_3+H_2$. N. Pfanner
studied the action of manganese on soln. of **hydroxylamine salts**—*vide infra*,
complex salts of manganous chloride and sulphate. J. J. Sudborough observed that
manganese is only slightly attacked when heated for some days in **nitrosyl chloride.**
When manganese is heated in **nitric oxide,** at a temp. below the decomposition
point of the gas, E. Müller and H. Barck found that the metal acts on nitric oxide

at 300°, and that there is a 68 per cent. decomposition at 400°, and complete decomposition at 500° ; some nitride is formed at 400°. F. Emich found that it yields a product similar to that obtained by heating it in oxygen. According to A. Guntz, pyrophoric manganese at a gentle heat burns in a current of **nitrogen peroxide**, forming manganese monoxide. dioxide, and nitride. C. Brunner showed that conc. **nitric acid** reacts with powdered manganese with incandescence and a feeble explosion ; while dil. nitric acid dissolves the metal, as was also observed by O. Prelinger, and E. Glatzel. H. Moissan said that pyrophoric manganese is made incandescent by drops of conc. nitric acid. According to C. Montemartini, when manganese dissolves in nitric acid, ammonia is formed, as well as nitrogen and nitrous oxide, and so much hydrogen that the evolved gas will not explode until oxygen has been added. A. N. Campbell found that with nitric acid of different concentrations the percentage composition of the gas was as follows :

		Gas		
Nitric acid	NO_2	NO	N_2O	H_2
100 per cent. .	100	—	—	—
50 ,, .	68	16	16	—
25 ,, .	0·1	39	20	40
12·5 ,, .	—	13	1	86

C. C. Palit and N. R. Dhar found that the reaction of manganese with 13 and 26 per cent. nitric acid is rapid with or without nitrous acid. B. Pelletier, and H. Moissan observed that manganese reacts directly with **phosphorus** when a mixture of the two is heated, forming manganese phosphide (q.v.). H. Moissan observed that pyrophoric manganese burns when heated in a current of the vapour of **phosphorus pentachloride**. E. Wedekind obtained an arsenide by heating manganese with **arsenic** ; and with **antimony** an antimonide is formed. O. Prelinger, and A. N. Campbell found that manganese reduces arsenic from a warm soln. of an **arsenic salt** ; antimony is likewise separated from a warm soln. of an **antimony salt** ; and bismuth from a warm soln. of a **bismuth salt**. H. E. Patten observed that manganese is blackened by **arsenic trichloride** ; but is not acted upon by **antimony pentachloride**.

As noted by J. F. John, manganese readily unites with **carbon,** forming a carbide (q.v.) ; and O. Ruff and co-workers found that the solubility of carbon in manganese increases slowly up to 7·12 per cent. as the temp. rises from 1360° to 1525°, the b.p. of the soln. at 30 mm. press. K. Kido studied this subject—vide the carbide. O. Meyer observed that manganese is attacked by **carbides**—silicon, chromium, and molybdenum—at 1600°. A. Westgren and G. Phragmén said that carbon dissolves in manganese the same way as in iron, not by replacing atoms of the metal in the space-lattice, but by lying between them. J. Paunescu observed that when manganese is heated in **methane,** manganese carbide is formed. E. W. Kanning and O. W. Brown studied the catalytic decomposition of heated **kerosene** by manganese. A. P. Lidoff observed that **cyanogen** is readily occluded by manganese. R. Lorenz and F. Heusler, and A. Guntz observed no formation of manganese carbonyl when the metal or carbide is heated in **carbon monoxide.** W. Heller found that manganese begins to react with carbon monoxide at 330°, and at 350° the reaction is fast, and very fast at 410°. He also made some preliminary observations on the equilibrium conditions. J. Backmann found that non-pyrophoric manganese burns readily in carbon monoxide at a red-heat ; and A. Guntz represented the reaction with pyrophoric manganese : $Mn+CO=MnO+C+33.3$ Cals. L. Troost and P. Hautefeuille found that carbon monoxide is less soluble than hydrogen in the different varieties of cast-iron, and that its solubility is diminished or even annulled by the presence of manganese. According to R. Lorenz and F. Heusler, **carbon dioxide** reacts with strongly heated manganese, forming manganese monoxide and carbon monoxide ; A. Guntz represented the reaction : $2Mn+CO_2=2MnO+C+46.3$ Cals. E. Müller and H. Barck found that a mixture of carbon dioxide and hydrogen passed over

manganese at 800° furnished some manganese carbide and manganous oxide. According to T. Bergman, water holding carbon dioxide in soln. dissolves manganese. H. E. Patten found that manganese is attacked by **ethyl chloride,** and by **chloroform,** but not by **carbon tetrachloride.** O. Warburg examined the effect of **hydrocyanic acid** on the catalytic activity of manganese in the oxidation of cysteine. According to A. Gautier and L. Hallopeau, when manganese is heated to 1400° in a current of **carbon disulphide,** a black layer of manganese sulphide and carbide is formed. C. Brunner, and O. Prelinger observed that the metal is dissolved by **acetic acid** with the evolution of hydrogen. L. Gay and co-workers found that when dry bromine is added to finely-divided manganese suspended in **ether,** and the mixture warmed on a water-bath, a complex bromide, $MnBr_2.(C_2H_5)_2O$, is formed; and bromine attacks **benzene** at 90°, but if manganese is present the attack begins at 75°. L. L. Steele studied the action of manganese compounds on the drying of linseed oil. O. Schmidt, and A. Korczynsky discussed its use as a catalyst in the hydrogenation of organic substances. C. Fromageot discussed manganese salts as catalysts for organic oxidations. H. Moissan found that manganese forms a boride when it is heated with **boron** ; and A. Guntz showed that when heated with **boron trichloride,** manganese chloride and boride are formed. H. Moissan observed that manganese unites directly with **silicon** at a high temp. to form a silicide (*q.v.*). R. E. Nyswander and B. E. Cohn studied the thermoluminescence of zinc borate glass activated with manganese. M. Levin and G. Tammann said that manganese destroys **porcelain** at a high temp. H. E. Patten observed no action with **stannic chloride.**

The action of manganese on the **metals** is discussed below. O. Prelinger found that soln. of many **metal salts** are reduced to the metal when warmed with manganese—*e.g.* copper, zinc, cadmium, tin, lead, chromium, iron, cobalt, and nickel salts ; A. N. Campbell found that manganese readily displaced tin, lead, copper, iron, nickel, cobalt, cadmium, and zinc from soln. of their salts. H. Schild observed the reduction of iron salts ; and N. W. Fischer observed that salts of only silver and gold were reduced to the metal by manganese. H. D. Royce and L. Kahlenberg found that manganese will replace from their salt soln. zinc and other metals which have more positive electrode potentials. With soln. containing 50 grms. of salt per litre, at 25°, manganese rapidly replaces the metal in soln. of zinc sulphate and chloride, cadmium sulphate, ferric chloride, cobalt chloride, nickel chloride, lead acetate, silver acetate, and copper sulphate ; and at 50° it slowly replaces the metal in lead nitrate, copper nitrate, and silver nitrate. O. Prelinger found that manganese gives hydrogen when it is heated with a soln. of **sodium hydroxide ;** but A. N. Campbell observed no perceptible action when manganese is boiled with a conc. soln. of soda-lye or potash-lye. H. Moissan found that manganese reacts with molten **calcium oxide,** forming manganous oxide, but much manganese is at the same time volatilized. For the action of manganese on **ferrous oxide,** *vide* ferrous oxide. C. H. Herty and O. S. True, and G. Röhl studied the reversible reaction with **ferrous sulphide** : $FeS+Mn \rightleftharpoons MnS+Fe$.

Some reactions of analytical interest.—There are compounds of manganese in which that element is bi-, ter-, quadri-, sexi-, or septi-valent. The compounds of bivalent manganese are considered here. The others are discussed later. The manganous salt soln. give no precipitate with **hydrochloric acid ;** and soln. acidified even with weak acids like formic, acetic, or succinic acid give no precipitate with **hydrogen sulphide,** and neutral soln. are incompletely precipitated, if at all, by that reagent. According to H. W. F. Wackenroder,[3] if ammonia be present, flesh-coloured hydrated manganese sulphide is precipitated ; and a similar precipitate is obtained with **ammonium or alkali sulphide.** The precipitate is insoluble in an excess of the alkali sulphide, but is soluble in conc. acetic acid. The soln. turns brown on exposure to air. The precipitate is black if a trace of iron be present. A soln. of **alkali hydroxide** gives a white precipitate of manganous hydroxide, which gradually becomes brown in air owing to the formation of manganese manganite,

or hydrated manganese dioxide, $MnO(OH)_2$. The oxidation is also effected by chlorine, bromine, hypochlorites, hydrogen dioxide, etc. F. Jackson estimated that 1 part in 128,000 can be detected by soda-lye. With aq. **ammonia** half the manganese is precipitated as white hydroxide and half forms a complex salt: $2MnCl_2 + 2NH_4OH = Mn(OH)_2 + (NH_4)_2MnCl_4$, and if sufficient ammonium chloride is present, hydroxide is precipitated, since all the manganese remains in soln. as complex chloride. The ammoniacal soln. absorbs oxygen from the air, forming a precipitate of the hydrated dioxide, $MnO(OH)_2$. F. Jackson estimated that 1 part in 64,000 can be recognized by the aq. ammonia test. White manganous carbonate is precipitated by **alkali carbonates**, and when boiled for a long time with water, the precipitate passes into hydrated manganese dioxide; **ammonium carbonate**, even in the presence of ammonium salts, precipitates the white carbonate; but **calcium carbonate**, according to J. N. von Fuchs, gives no precipitate in hot or cold soln.; H. Demarçay said that the three **alkaline earth carbonates**, and **magnesium carbonate** give no precipitate in cold soln., but precipitation is complete with boiling soln.; and J. W. Döbereiner added that magnesium carbonate precipitates the manganese completely in boiling soln.—magnesia acts similarly but more quickly. E. Bauch made some observations on this subject. Normal manganous phosphate is precipitated by **sodium phosphate**, and it is soluble in mineral and acetic acids. If ammonia be added to the boiling acid soln. of the precipitate, pink scales of ammonium manganous phosphate are precipitated. With **sodium arsenate** a white precipitate of manganous arsenate is deposited. With **potassium cyanide** a brownish precipitate is first formed; it then dissolves to produce a brown soln. When the soln. is warmed, or allowed to stand for some time, a green precipitate of $KMnCy_3$ is formed, and this dissolves in more potassium cyanide to form a yellow soln. of K_4MnCy_6. If the dil. soln. be boiled it is decomposed, and manganous hydroxide is precipitated, but ammonium sulphide gives no precipitate if a large proportion of potassium cyanide is present. The dil. soln., however, deposits manganese sulphide when boiled. With **potassium ferrocyanide**, C. H. Pfaff said that a white precipitate, soluble in hydrochloric acid, is formed even with 1 part of salt in 6000 parts of water. F. J. Otto found that the precipitate is not soluble in an excess of ferrocyanide, ammonium chloride, or other salts; with **potassium ferricyanide** a brownish-yellow precipitate, insoluble in hydrochloric acid, is produced. According to P. Berthier, **potassium sulphite**—not ammonium sulphite —gives a precipitate of manganous sulphite when boiled. No precipitation occurs with **potassium chromate**. D. Vitali found that dil. sulphuric acid and **potassium bromate** give a gradually increasing reddish-violet colour, due to the formation of permanganate—chlorates and iodates do not give the reaction. When boiled with **potassium chlorate** in nitric acid, hydrated manganese dioxide is formed. A deep red precipitate is produced with **potassium periodate**. Conc., not dil., soln. of manganous chloride give a precipitate with **oxalic acid**; the precipitate is not soluble in an excess of the acid, but it is soluble in hydrochloric or sulphuric acid; **alkali oxalates** give a precipitate in conc. or dil. soln., but not in the presence of ammonium chloride or a large excess of the alkali oxalate. According to G. Denigès, 5 c.c. of the manganese sat. soln. is treated with a few drops of sodium hydroxide soln., and shaken until a brown coloration is obtained; sat. oxalic acid soln. is then added drop by drop. The brown coloration disappears and is replaced by the red coloration characteristic of manganese salts. The reaction was also studied by H. Caron and D. Raquet. No precipitate is formed with **alkali succinate or benzoate**, or with **tincture of galls**. According to J. Volhard, if a soln. containing traces of manganese be boiled with **lead dioxide** and conc. nitric acid, diluted with water, and allowed to settle, the supernatant liquid has a violet-red colour, due to the formation of permanganate. The presence of chlorides hinders the formation of the permanganate. The reaction was studied by H. Baubigny; H. Marshall used **ammonium persulphate** in the presence of silver nitrate as oxidizing agent; and by its means 0·001 mgrm. of manganese per c.c. can be detected. According to A. Trillat, a soln. of **tetra-**

methyldiaminodiphenylmethane in acetic acid gives a deep blue colour with lead and manganese dioxides. This reaction is extremely delicate and may be used for the detection of these metals. The reagent is prepared by boiling 30 grms. of dimethylaniline with 10 grms. of formaldehyde and 200 c.c. of water. After cooling, the liquid is made alkaline with sodium hydroxide and a current of steam is blown through until the excess of dimethylaniline is expelled. On cooling, crystals separate, which should be recrystallized from alcohol. Five grams of the base are dissolved in 100 c.c. of water and 10 c.c. of acetic acid ; the soln. must be placed in a well-stoppered bottle and preserved in the dark.

The physiological action of manganese.—Manganese compounds appear to play an important part in many biochemical changes. The subject was discussed by G. C. Gmelin.[4] G. B. Davis and W. B. Huey reported two cases of chronic manganese poisoning with men working an electric furnace melting ferromanganese. F. Wohlwill observed that the salts cause capillary hyperæmia of the alimentary canal. H. Micheels and P. de Heen found that colloidal soln. of manganese have a more stimulating action on germinating seeds than similar soln. of tin. G. Salomone found that while a certain quantity of manganese has a beneficial influence on the development of the plant as a whole, large quantities are toxic. The toxic effect of manganic salts is greater than that of manganous salts, and is dependent on the amount of dissociation, so that it is naturally greater for the salts of the more highly ionized mineral acids than for those of the organic acids ; in other respects the poisonous effect is but slightly influenced by the nature of the anion. The very marked poisonous properties of barium manganate and permanganate are attributed to the combined influence of the barium and the manganese. Manganic acid is more poisonous in the free state than in combination. Small quantities of manganous iodide exert a favourable influence on the germination of cabbage or carrot seeds. Of the manganese salts tried, manganous sulphate and nitrate and manganese dioxide were found to exert the most beneficial action on the growth of corn. As indicated in connection with the occurrence of manganese, G. Bertrand and co-workers assumed that manganese is an essential, not an accidental constituent of plants ; it is of vital importance in the extraction of oxygen from the air whenever this is necessary for producing the various chemical changes required for the vital activity of the plant. G. Bertrand found that the latex of the *Rhus succedanea* is first white, and on exposure to air it becomes brown, and then black. The latex contains laccase, laccol, and water. The laccol forms an emulsion with the soln. of laccase in water. The laccase contains the manganese and acts as a carrier of oxygen to the laccol. Laccol is not present in all plants, but its place is taken by analogous substances—*e.g.* tannin, boletol, etc.

Experiments showing that the presence of small proportions of manganese salts in soils favoured the growth of plants, whereas larger proportions may be injurious, were cited by T. Pfeiffer and co-workers, J. J. Skinner and M. X. Sullivan, J. Stoklasa, P. Leidreiter (sugar beets, mangolds, potatoes, oats, and beans), K. Aso (radishes, barley, wheat, and peas), O. Loew and S. Honda (*Cryptomeria japonica*), O. Loew and S. Sawa (barley, rice, peas, and cabbage), P. Pichard, J. Schroeder, E. Ramann, H. Birner and B. Lucanus, P. Wagner, I. Giglioli, N. Ono, H. Molisch, A. Grégoire and co-workers (potatoes and sugar-beet), Y. Fukutome (flax), J. A. Voelcker (wheat and barley), T. Katayama (barley), M. Nagaoka (rice), W. van Dam, W. F. Sutherst (maize), J. S. McHargue, and E. P. Deatrick (wheat), C. Montemartini, R. Ricci and G. Barbera, A. Bartmann, and G. Masoni, G. d'Ippolito (wheat, maize, and lucerne), F. A. Sannino and A. Tosatti (vines), L. Hiltner and G. Korff (oats), I. Namba (onions), M. de Molinari and O. Ligot (oats and barley), A. Carlier (grass, potatoes, and mangolds), O. Schreiner and P. R. Dawson (wheat, rye, corn, and potatoes). G. Leoncini observed the favourable effects of manganese dioxide in soils on nitrification. G. Spampani, and L. Bernardini attributed the beneficial effect of manganese to the production of soluble calcium and magnesium compounds from insoluble forms, so that it is an

indirect calcium-magnesium manure.   H. von Feilitzen found that with oats 10 kgrms. of manganese sulphate per hectare had no effect ; and S. Rhodin found that with oats one kgrm. of manganese peroxide per acre reduced the yield, and 6 kgrms. per hectare also reduced the yield with potatoes.   J. A. Voelcker obtained nugatory results with wheat ; F. Weis, and P. Ehrenberg and O. Nolte observed no change in the ash of plants ; and H. Vageler observed no stimulation with oats, lupins, and beans.   P. Nottin discussed the absorptive power of soils for manganese salts.   P. E. Brown and G. A. Minges found that manganese chloride applied at the rate of more than 2000 lbs. per acre retarded both ammonification and nitrification.   The applications of 100 and 200 lbs. increased ammonification slightly and nitrification distinctly.   Manganese sulphate increased both ammonification and nitrification when applied at the rate of 100 lbs. per acre, whilst a larger amount (2000 lbs.) has a depressing effect.   Manganese oxide applied at the rate of 2000 lbs., or more, per acre retards both ammonification and nitrification.   W. T. McGeorge observed no effect with manganese on the growth of sugar-cane.   According to N. L. Söhngen, the formation in the soils of higher oxides of manganese from manganous salts is promoted by a high concentration of hydroxyl ions, and the reduction of these oxides by the presence of peroxides, peroxydases, and oxydases. The presence of dextrose in the soil leads to the formation of hydroxy-acids capable of decomposing the higher oxides of manganese.   C. Montemartini found that 0·001 per cent. of manganese sulphate stimulated the respiration of vine plants, garden beans, and potato plants.   J. S. McHargue also considers manganese is a necessary constituent performing an important function in the synthesis of chlorophyll.   Similar ideas were held by A. Villiers, A. Livache, etc.   E. Houtermans could not confirm C. Acqua's statement that the roots of plants in contact with manganese nitrate secrete manganese in certain places in which the nitrogen is assimilated.   F. Plate showed that with *Triticum sativum* and *Hyacinthus orientalis* grown in soln. containing one of the following salts, manganese chloride, manganese bromide, manganese nitrate, and manganese sulphate, anion and cation, are absorbed in the same proportion as that in which they exist in the soln. ; the anion chiefly reaches the shoot, whilst the cation is found especially in the root.   According to A. Rippel, the addition of soluble manganese salts to the cultures in which oats seedlings were growing produced a chlorosis which was remedied by the addition of iron.   Since the iron content of the chlorotic and normal seedlings was the same, it is concluded that manganese does not prevent the uptake of iron by the plant, but inhibits its action after absorption.   H. Coupin found a 1 : 1000 soln. of manganous chloride is toxic to wheat.   M. O. Johnson observed that manganese sulphate and dioxide caused the chlorosis of pine-apples.

O. Loew and S. Sawa observed no decided stimulating action of manganese on yeast and aspergillus.   E. Kayser and H. Marchand found that when manganese sulphate is added to fruit musts which are to be fermented with yeast, there is an increase in the amount of alcohol, glycerol, and acids formed, but the initiation of fermentation occurs later the greater the amount of manganese sulphate added.   Manganese lactate and acetate produce practically the same effect as the sulphate when added in equivalent quantity, but the phosphate and succinate lead to the production of less alcohol and more glycerol.   With manganese nitrate fermentation sets in rapidly, and the amount of sugar consumed is about the same as when manganese sulphate is added.   The addition of potassium nitrate to the must leads to a smaller consumption of sugar than when yeast is used alone.   G. Bertrand and M. Javillier, and H. I. Waterman found that manganese sulphate favoured the development of *Aspergillus niger*; indeed, G. Bertrand found that one part of manganese in 10,000,000,000 parts of an artificial culture medium had an appreciable effect in increasing the yield.   M. Rosenblatt and A. J. March found that manganese salts sometimes stimulate alcoholic fermentation and sometimes inhibit the reaction— dependent on the origin of the yeast.   The inhibitory action is independent of the medium or the form in which the manganese is added (sulphate or nitrate), but the

different results with different types of yeast indicate that the sensitivity of the enzymes produced by the yeast changes with the origin of the yeast and with the composition of the medium. Increasing the concentration of sugar protects the enzymes against the manganese, and thus exerts a weakening effect on both the manganese activation and inhibition of the fermentation reaction. D. Olaru observed that one part of manganese in 200,000 parts of medium is favourable to the fixation of nitrogen by the bacteria of *leguminosæ*. The addition of a minute amount of manganese was found by G. Bertrand, and A. Bach to increase the activity of the enzyme laccase, and colloidal manganese dioxide was found by B. Sjollema to act like an oxydase towards guaiacum tincture, and hydroquinone. The processes appear to be regulated by colloidal enzymes. E. J. Witzemann has suggested that the effect of manganese on enzymic activity is due to the effect of the colloidal hydrated dioxide on the physical character of the enzyme, so that if the colloidal dioxide keeps the colloidal enzyme under conditions normally unfavourable to this effect, a positive influence on enzymic activity would be produced. J. B. Garner and W. E. King observed that $\frac{1}{158}N$-permanganate soln. is antiseptic, and $\frac{1}{511}N$-soln. is germicidal towards *Bacillus typhosus*.

The occurrence of manganese in animals has been previously discussed. G. M. Piccinini [5] found that the addition of manganese to the ordinary diet causes an increase in the iron-content of the liver and spleen, and the absorption of iron appears to be regulated by the manganese available in the body. Colloidal manganese augments *in vitro* the available oxygen of blood, and maintains this increase for some time. It seems also to have the same action *in vivo*. Colloidal manganese retards the death of guinea pigs injected with the minimum lethal dose of diphtheritic toxin. A. Trillat found that the action of a manganous salt in alkaline soln. as a carrier of oxygen is largely increased by the addition of a small proportion of proteid matter—*e.g.* white of egg. The stimulating action is attributed to its tendency to prevent the precipitation of the manganese dioxide, which is thus maintained in a colloidal state, and is consequently more chemically active. Beyond a certain limit, an increase in the amount of albumin does not accelerate the oxidation; the maximum effect is produced when one part of albumin is added to 1000 parts of the mixture, and the addition of mercuric chloride, arsenic acid, prussic acid, formaldehyde, etc., has a paralysing effect similar to that observed in the case of a soln. not containing albumin. Other proteids, such as horse-serum, and colloids, such as gelatin, dextrin, and gum arabic, have given very variable results. G. Cohn showed that the presence of manganese interferes with artificial digestion by means of pepsin. C. Richet and co-workers found that the same daily dose of manganese citrate has a slightly harmful effect and the same dose every fourth day a slightly beneficial effect on dogs. J. S. McHargue found that a diet containing manganese improved the growth of rats. He found that manganese occurs in largest proportions in plant and animal tissues showing the greatest vitamin potency, and he suggested that there is a relationship between manganese and these vital factors. G. Bertrand and F. Medigreceau found that with repeated subcutaneous injections of minute doses of manganese sulphate in four rabbits there was a marked loss in weight, and three injections of 5 mg. of manganese per kilo. of body-weight, at intervals of twenty-four hours, caused the death of the rabbit. When the manganese is subcutaneously injected, it is rapidly diffused throughout the body, and all the tissues, including the nervous tissue, become temporarily impregnated. It is readily eliminated through the liver, bile, and mucus of the alimentary canal, and a small quantity is excreted in the urine. F. Medigreceau found that the amount of manganese in transplanted mouse and rat tumours is small (0·004 to 0·012 mgrm. per 100 grms. of fresh material), which is about the same as in the normal mammary gland of the mouse. No difference in the manganese of sarcoma and carcinoma was discoverable. According to C. K. Reiman and A. S. Minot, the prolonged administration of manganese to dogs failed to produce any significant changes in manganese content of blood or tissues,

or to cause any pathological symptoms. According to H. Handovsky and co-workers, acute manganese poisoning occurs only when the conc. of manganese in the blood suddenly becomes very high, and is accompanied with nervous disturbances. In chronic poisoning this high conc. is not reached, nervous symptoms are not observed, the liver is chiefly attacked, and death occurs usually with smaller amounts than in acute poisoning, the lethal doses being 40 mgrms. per kgrm. In the chronic condition manganese citrate is more rapidly absorbed and more poisonous than the chloride. About 50 per cent. of the manganese injected is excreted in the faeces, but only traces appear in the urine. Considerable amounts of manganese are found in bone, bile, pus, and ascitic fluid. In the organs most manganese is deposited in the spleen and brain, a variable quantity in the liver, and only a little in the lungs. Manganese is found in muscle only after injection of the chloride, and not of complex organic salts of manganese. Fatty degeneration of the liver, heart, and kidney sometimes occurs. The subject was discussed by J. Cahn, F. Bergamo, E. Harnack and F. Schreiber, R. F. Gayle, D. Vitali, J. R. Charles, W. F. von Oettingen and T. Sollmann, etc. J. S. McHargue, and G. Bertrand and H. Nakamura found that manganese stimulates the growth of rodents. E. F. Hopkins found that manganese is essential for the growth of *Corella*. The optimum concentration is approximately 1 in 5×10^6; at higher concentrations, say 1 in 5×10^4, there is a toxic effect.

J. W. H. Harrison and F. C. Garrett found that melanism is induced in the *Lepidoptera* by manganese feeding, but H. M. Fox and H. Ramage did not find manganese to be particularly associated with melanin. The spectrum of the ink sac of *Sepia* showed no manganese; whilst that element is present to the extent of 0·008 per cent. of the dry weight of the black body wall of the Arion, but there is even more in the colourless, common genital duct.

Some uses of manganese.—It has been estimated that 90 to 95 per cent. of the world's consumption of manganese is used in the manufacture of steel—*manganese steels*—not only to deoxidize and recarburize the molten metal so as to make cleaner and sounder ingots, but also to impart strength, hardness, and other qualities to the finished product. The manganese is introduced in the form of special alloys with a percentage ratio of Mn, Fe, Si, and C respectively as follows: *ferromanganese*, 50 to 80, 40 to 8, 0·5 to 1·5, and 5 to 7; *spiegeleisen*, 10 to 35, 85 to 60, about 1·0, and 4 to 5; *silicomanganese*, 55 to 70, 20 to 5, about 25, and 0·35; and *silicospiegel*, 20 to 50, 67 to 43, 4 to 10, and 1·5 to 3·5.[6] There is an alloy called *manganese bronze*, which is a kind of brass to which has been added a small proportion, say 0·05 per cent., of manganese, along with small proportions of iron, aluminium, tin, and lead for strengthening the alloy, and making it denser and closer grained than the average yellow-brass casting. The composition approximates 57·0 to 59·0 per cent. Cu; 38·0 to 40·0 Zn; 0·25 to 1·0 Fe, Mn, Al, and Sn; and 0·10 to 0·50 Pb.[7] The object is to produce a metal suitable for marine construction and mining machinery and wherever corrosion is a serious difficulty. There is also a series of *magnetic alloys* obtained by alloying manganese with aluminium, tin, arsenic, antimony, bismuth, and boron. They are sometimes called *Heusler's alloys*.[8]

Some of the manganiferous earths—*e.g.* wad—are used as pigments. Manganese dioxide was formerly used in the manufacture of chlorine, but the process was largely displaced by electrolytic methods. Manganese dioxide is employed in making up the dry cell, when the dioxide serves to depolarize the hydrogen. Manganese oxide is used in bleaching glass—*vide supra*, the history of manganese—or in colouring glass.[9] It is also used to impart purple tints to glasses and pottery glazes; to produce brown glazes, and "rockingham" glazes on red bodies; and for tinting brick clays. Manganese dioxide and various manganese salts—sulphate, borate, resinate, linoleate, and oxalate—are added as driers to linseed and other oils to make them capable of absorbing oxygen from the air during the so-called drying of the oil. Manganese chloride is used in dyeing; manganese

sulphate, in calico printing, etc.; manganese persulphate is used as an oxidation agent in making organic products; and manganates or permanganates are used for preserving wood, for bleaching textile fibres, and for disinfecting [10] and oxidizing purposes.[11]

§ 6. The Atomic Weight and Valency of Manganese

W. Manchot [1] and co-workers, and G. Grube and W. Brause discussed complex salts of *univalent* manganese. In manganous salts the manganese behaves as a *bivalent* element; thus, when dissolved in bismuth trichloride or in urethane, manganous chloride has a mol. wt. corresponding with the formula $MnCl_2$. Manganous sulphate is isomorphous with the analogous sulphates of zinc and magnesium; and manganous carbonate is isomorphous with calcium and magnesium carbonates. Manganese is *tervalent* in the manganic salts; thus in manganic acetylacetonate the vapour density and the mol. wt. in benzene correspond with the formula $Mn(C_5H_7O_2)_3$; and in the manganic alums the salts are isomorphous with those containing tervalent aluminium. J. Meyer and W. Schramm, and G. A. Barbieri discussed the tervalent manganese compounds. Manganese is probably *quadrivalent* in the salts $2KF.MnF_4$, $2KCl.MnCl_4$, etc., of E. Weinland and O. Lauenstein, A. Yakimach, R. J. Meyer and H. Best, G. Neumann, and W. B. Holmes and E. V. Manuel. In the dioxide also the manganese may be quadrivalent, as advocated by L. Marino, $O=Mn=O$, or it may be bivalent:

$$Mn\big<{{O}\atop{O}}$$

In the manganates, manganese is probably *sexivalent*, since potassium manganate, K_2MnO_4, is isomorphous with the sulphate, K_2SO_4; and the manganese is probably *septivalent* in the permanganates. This is in agreement with the isomorphism of the permanganate, $KMnO_4$, and the perchlorate, $KClO_4$.

In seeking resemblances between the elements, the isomorphism rule can easily be pushed too far—*qui nimium probat, nihil probat*. It has been said that although a great many facts can be cited in establishing a relation between isomorphism and the position of an element in the periodic table, yet facts show that there may be isomorphous compounds amongst quite different groups of elements in the periodic table. Thus, it could be argued that iron belongs to the sulphur family because of the isomorphism between potassium ferrate and the corresponding sulphate. Lead is placed with carbon in spite of the absence of isomorphous compounds and of its isomorphism with the alkali family. The isomorphism of the sulphates and tellurates and of the sulphides and tellurides indicates that tellurium belongs to the sulphur family, although the isomorphism between K_2TeCl_6, K_2OsCl_6, and K_2IrCl_6 would make tellurium a member of the eighth group, and a similar agreement applied to Cs_2SnCl_6 and Cs_2TeCl_6 and to potassium tellurium and potassium zirconium oxalates would make tellurium a member of the tin family. The isomorphism between $KMnO_4$ and $KClO_4$ favours placing manganese in the seventh group, but the isomorphism of K_2MnO_4 and of K_2SO_4 would agree with manganese in the sulphur group, and the analogies between manganese and tin tetrachlorides would put manganese and tin in the same family. Platinum would be grouped with tin and lead if we were guided by the isomorphism of the plumbates, stannates, and platinates. The establishing of a family likeness between elements because of the isomorphism of some of their compounds is unscientific and arbitrary. Isomorphism

seems to depend more on a similarity of chemical constitution than on family resemblances of the elements concerned.

D. I. Mendeléeff's arguments [2] for placing manganese in the seventh group of the periodic table were based mainly on the maximum heptavalency of the element, *e.g.* the apparent similarity of the chlorine and manganese dioxides and of the perchlorates and permanganates, although by the same argument it could be argued that vanadium has a place in that group because of the apparent similarity between the chlorates and vanadates. The arguments based on isomorphism are similarly open to question. F. R. von Bichowsky argued that it would be better to place manganese with the iron family in the eighth group, because (1) manganese is at the end of the Ti, V, Cr row, the titanyl, vanadyl, and chromyl salts, and these salts become more stable in that order ; consequently, stable manganyl salts might be anticipated, but this is not the case ; (2) while the barium salts of titanic, vanadic, and chromic acid are all slightly soluble, barium permanganate is very soluble ; (3) titanium, vanadium, and chromium form per salts, but manganese does not form a higher per salt than the permanganates ; (4) the titanates, vanadates, and chromates are stable in alkaline soln. and unstable in acid soln. ; permanganates are more stable in acid soln. ; (5) the titanous, vanadous, and chromous salts are powerful reducing agents ; (6) the manganous halides are isomorphous with the ferrous halides, but not with the chromous halides ; (7) the hydrates of manganous chloride are isomorphous with those of cobalt ; and the manganous salts and the corresponding salts of the iron family closely resemble one another, but not so with the manganous salts of the titanium, vanadium, and chromium group ; (8) there is a marked contrast with the sulphides : manganese sulphide belongs to the iron group rather than to the other group ; (9) similar remarks apply to the carbonates ; likewise (10) the ferric, manganic, cobaltic, and nickelic salts are all oxidizing agents, but the corresponding salts of titanium, vanadium, and chromium are reducing agents; (11) the metal alloys also favour placing manganese with iron ; likewise also (12) the carbides and silicides ; and (13) the colours of salts with the different valencies of manganese favour the view that the normal valency of manganese is even, not odd. All this, of course, is purely circumstantial evidence, and it can be matched with arguments of a similar type for the opposition. The subject was discussed by M. M. Gerber.

J. Dalton [3] estimated the atomic weight of manganese to be 40 when that of oxygen is 7. In 1813, from the observations of previous workers, J. J. Berzelius said that it appeared as if manganese forms a series of oxides with manganese and 1, 2, 4, 6, and 8 at. proportions of oxygen; and later he gave 711·57 for the at. wt. when that of oxygen is 100. This reduces to 113·85 if the at. wt. of oxygen be 16. In 1818, he represented the oxides Mn : O=1 : 2, 1 : 4, and 3 : 8. The at. wt. was halved, and then the at. wt. was represented by 56·93 ; and later by 55. J. J. G. Meinecke, in 1817, and T. Thomson, in 1822, represented the at. wt. by 56 ; C. G. Bischof, in 1819, gave 2×56·93 ; L. Gmelin, and C. M. Despretz, in 1826, gave 28, or ½ of 56, for the eq. wt. ; L. J. Thénard, in 1826, gave 57·02 ; P. T. Meissner, in 1834, 55·43 ; and O. B. Kühn, in 1837, gave 27·7 for the eq. wt. Observations were also made by J. F. John, G. Forchhammer, and H. Davy. A number approximating 55 fits in with Avogadro's theory extended to soln. ; with the sp. ht. rule , with the isomorphism rule for compounds of bivalent Mn, Mg, Zn, Fe, Co, and Ni; for compounds of tervalent Mn, Al, Ga, In, Tl, Ti, V, Cr, Fe, Co, and Rh ; for sexivalent Mn, S, Se, Cr, Fe, and probably Mo and W ; and septavalent Mn and Cl. The position assigned to manganese in the seventh group of the periodic table along with the halogens is not so good. The septavalency of manganese in Mn_2O_7 and of chlorine in Cl_2O_7 is usually over-emphasized in attempting to justify the association of manganese with the halogens in the periodic table. It is much more closely related with the iron family of elements in the eighth group elements. The subject was discussed by E. H. Büchner, J. Parry, H. Reynolds, F. R. von Bichowsky, R. G. W. Norrish, G. Oddo, and H. Teudt.

The relation between the affinity and density of the elements was discussed by E. Donath and J. Mayrhofer; between the affinity and decomposition temp. of the amines, by F. Ephraim, W. Biltz, and A. Werner, and they obtained the order $Ni > Co > Fe > Mn > Cu > Cd > Zn > Mg$; between the affinity and the heats of formation of various compounds, by H. Moissan, and M. Berthelot, and they obtained the order Cr, Mn, Fe, Co, and Ni.

In 1810, J. J. Berzelius oxidized manganese with nitric acid, and after converting the nitrate to oxide, obtained the at. wt. 56·7 from the assumed ratio $2Mn : Mn_2O_3$. The number is a little too high; presumably some Mn_3O_4 was also present. If the data be calculated for the ratio $Mn_3 : Mn_3O_4$, it gives 50·4. R. Brandes, from the analysis of the chloride, $MnCl_2.nH_2O$, obtained the at. wt. 57. J. A. Arfvedson's data gave 55·9 for the ratio $MnCl_2 : 2AgCl$; and from the same ratio J. J. Berzelius obtained 54·88; E. Turner, 54·9; and G. P. Baxter and M. A. Hines, 54·932. J. B. A. Dumas obtained 54·92 from the ratio $MnCl_2 : 2Ag$; J. Dewar and A. Scott, 54·85; and G. P. Baxter and M. A. Hines, 54·934. G. P. Baxter and M. A. Hines also calculated 54·930 from the ratio $MnBr_2 : 2AgBr$. E. Turner calculated 56·0 from the ratio $MnCO_3 : CO_2$; E. R. Schneider, 54·03 from the ratio $MnC_2O_4 : 2CO_2$; and 54·08 from the ratio $Mn_3O_4 : H_2O$. E. Turner obtained 56·0 from the ratio $MnO : MnSO_4$; J. J. Berzelius, 55·28, J. C. G. de Marignac, 55·07, and J. M. Weeren, 55·01. C. von Hauer obtained 54·90 from the ratio $MnSO_4 : MnS$, and J. M. Weeren, 55·02. C. von Hauer calculated 55·02 from the ratio $3MnO : Mn_3O_4$; J. Dewar and A. Scott, 54·91 from the ratio $AgMnO_4 : (Ag+MnO)$, and 54·938 from the ratio $AgMnO_4 : KBr$. Assuming that the at. wts. of silver are 107·880, 107·876, and 107·871, B. Brauner (1913) computed 54·932, 54·930, and 54·927 respectively for the best representative values of the at. wt. of manganese. L. Meyer and K. Seubert (1883) computed 54·8 for H unity; and F. W. Clarke (1910) gave 54·947 for the best representative value. The International Table for 1927 gave 54·93.

The **atomic number** of manganese is 25. P. Vinassa discussed the molecular numbers of compounds of manganese. No **isotopes** of manganese have been observed.[4] The **atomic disruption** of the atom has not yet been observed by E. Rutherford and J. Chadwick, or by H. Pettersson and G. Kirsch. A. L. Foley made experiments on this subject. The **electronic structure,** according to N. Bohr, is (2) for the K-shell; (4, 4) for the L-shell; (4, 4, 5) for the M-shell; and (2) for the N-shell. The subject was discussed by H. Collins, J. D. M. Smith, S. Meyer, R. N. Ghosh, D. M. Bose, B. Cabrera, C. G. Bedreag, A. Sommerfeld, P. D. Foote, R. Ladenburg, C. D. Niven, R. Samuel and E. Markowicz, D. Avdalian, and by W. H. Rothery.

§ 7. The Alloys and Intermetallic Compounds of Manganese

R. von Gersdorff [1] made **copper-manganese alloys** about 1840. According to E. A. Lewis, the two metals can be readily alloyed in all proportions ; and he made the alloys by melting the mixed metals under a layer of borax ; S. F. Schemtschuschny and co-workers melted the mixed metals under a layer of barium chloride ; and R. Sahmen melted the mixture in an atm. of hydrogen. S. Wologdine melted the mixed metals under a layer of charcoal in a crucible lined with magnesia. F. Gloger melted copper oxide with an excess of manganese silicide and found that the silicon reduced the cuprous oxide, forming cupromanganese free from silicon. G. A. Dick melted a mixture of ferromanganese, copper, and silicon ; A. R. von Schrötter heated a mixture of copper hammer-slag, manganese dioxide, and carbon ; J. F. Allen heated a mixture of copper oxide, manganese oxide, and carbon ; C. Schwarz and A. Weishut used an analogous process ; while F. von Kügelgen reduced a mixture of copper oxide and chloride and manganese oxide by calcium carbide under a layer of calcium chloride. Analyses of commercial alloys were made by H. Winter, E. W. L. Biermann, and E. Priwoznik. The uses of the alloys were discussed by M. Levitzky, A. Carnot, L. Archbutt, N. Parravano, E. A. Lewis, and C. Heusler. G. Sirovich and A. Cartoceti showed that copper can be cemented by ferromanganese or chromomanganese. G. Sirovich and A. Cartoceti discussed the cementation of copper by chromomanganese with 30·4 per cent. of chromium and 63·8 per cent. of manganese. The chromium does not penetrate the copper, but it favours the penetration of manganese more than does the iron of ferromanganese. The segregation of alloys was discussed by G. Masing, O. Bauer and H. Arndt, and W. Dinkler.

S. Wologdine thought that there exists a compound *copper tetramanganeside*, $CuMn_4$, but S. F. Schemtschuschny and co-workers, and R. Sahmen showed that the two elements form a continuous series of solid soln. E. A. Lewis thought that the series was broken between 20 and 95 per cent. of copper. S. F. Schemtschuschny and co-workers represented the f.p. curve by Fig. 14, which has been modified by

E. Persson to suit his observations on the X-radiograms of the alloys. The curve is continuous, with a minimum at 868° and 35·5 per cent. manganese. At compositions 10 and 15 per cent. of manganese, the interval between the liquidus and solidus curves is a maximum, and the two curves coincide at the minimum. R. Sahmen confirmed these results, obtaining a minimum at 866° with 35 per cent. of manganese. E. C. Bain, and M. R. Andrews showed that the X-radiograms of the alloys indicate that there is a wide difference in the lattices of the limiting metals, and that there is a region from 60 to 90 per cent. manganese where the lattices overlap.

T. Ishiwara's results are summarized in Fig. 15. The liquidus curve $C'EM'$ agrees with the observations of S. F. Schemtschuschny and co-workers, and R. Sahmen, and the solidus agrees with the corresponding curve on R. Sahmen's diagram. T. Ishiwara found that alloys annealed at 830° containing less than 20 per cent. of manganese were homogeneous, but those with more manganese were heterogeneous. This is in agreement with the horizontal line ED, and the solidus DM', and the region for the solid soln. γ, which is bounded also by the curve M_2I, and the curve DJ. The eutectoid line is represented by FJK. The
Figs. 14 and 15.—Freezing-Point Curves of the System : Cu–Mn.

dotted curve cm represents the magnetic susceptibility of the alloys ; and $c'm'$, Rockwell's hardness. O. Bauer and H. Arndt discussed the segregation of the alloys.

R. Sahmen said that the alloy with 5 per cent. manganese is brass-yellow ; with 10 per cent. manganese, pale yellow ; and with 20 per cent. manganese, grey. H. Behrens added that the alloy with 10 per cent. manganese is reddish, and that with 30 per cent. manganese polishes tin-white. S. Wologdine also said that alloys with 0 to 40 per cent. manganese have a more or less reddish tinge, gradually becoming greyish-white. A. Valenciennes, and E. F. Dürre also made some observations on the colour of these alloys. H. Behrens said that the microstructure, after etching with aq. ammonia, shows a fine, irregular net-work ; and S. Wologdine added that heterogeneous dendrites of copper occur in alloys with up to 40 per cent. manganese, whilst alloys with 40 to 78 per cent. manganese have white, hard crystals in a dark matrix. R. A. Patterson found that in the formation of solid soln. by adding up to 30 per cent. to copper, the atoms of copper in the face-centred lattice are replaced by manganese atoms, with an increase in the side of the cube from 3·60 A. to 3·70 A. E. C. Bain discussed the X-radiograms. For S. Sekito's, E. Persson and E. Oehlman's observations, *vide supra*, manganese. Z. Nishiyama also studied the subject. E. Persson's observations on the parameter constants of the alloys are :

Manganese	0	16·9	41·5	77	84·0	90·2	92·7	96·4 at. per cent.
a in Cu-phase	3·607	3·670	3·730	3·742	—	—	—	— A.
γ-Mn { a	—	—	—	—	3·738	3·763	3·763	3·771 A.
{ c	—	—	—	—	3·713	3·629	3·617	3·556 A.
{ c/a	—	—	—	—	0·993	0·965	0·961	0·943 A.
β-Mn, a	—	—	—	—	—	6·304	6·302	6·212 A.
α-Mn, a	—	—	—	8·906	8·903	8·917	8·904	— A.

The results for the copper and γ-manganese phases are summarized in Fig. 16.
FIG. 16.—Lattice Parameters of the Copper and Manganese Phases.

A. L. Norbury gave for alloys with 2·40, 7·20, 15·37, and 31·08 per cent. of Mn, the sp. gr. 8·796, 8·564, 8·126, and 7·810 for the annealed metal, and for the first two samples after hammering, respectively 8·819 and 8·574. E. Münker observed that alloys with 0, 0·04, 0·19, 0·98, and 1·49 per cent. manganese had the respective sp. gr. 9·008, 8·905, 8·903, 8·860, and 8·820 at 4°. E. A. Lewis found the sp. gr. of the alloys at 15·5° to be :

Mn	1	5	10	15	20	25	30	40	50 per cent.
Sp. gr.	8·935	8·757	8·425	8·102	8·284	7·782	7·746	7·324	7·332

The alloys with higher proportions of manganese contained too many air-blebs to justify a determination of the sp. gr. E. Persson's curve for the at. vol. of the alloys is shown in Fig. 16. Z. Nishiyama obtained the following results between 16° and 18·3° for the sp. gr., and the elastic modulus, E kgrms. per sq. c m. :

Mn.	0	0·5	1	2	5	10	15	25 per cent.
Sp. gr.	8·9487	8·9084	8·8949	8·8792	8·8375	8·5127	8·3183	8·0072
$E \times 10^{-6}$	1·204	1·276	1·289	1·281	1·265	1·233	1·214	1·199

The hardness, in kgrms. per sq. mm., was found by S. Wologdine to be :

Mn	0	1·6	20	40	60	74·75	79·0	80·7	93·0 per cent.
Hardness	50	68·4	121	146	180	193	374	247	241

The curve rises irregularly but gradually with increasing manganese up to about 70 per cent., and it then rises rapidly up to 78 per cent. ; it subsequently falls up to 86·0 per cent. and thereafter rises again. S. F. Schemtschuschny and W. Petraschewitsch found that the hardness reaches a maximum with between 25 and 35 at. per cent. of copper. Observations were also made by R. Sahmen, L. Guillet, N. S. Kurnakoff and S. F. Schemtschuschny, H. Behrens, and A. Valenciennes. According to S. Wologdine, alloys with up to 40 per cent. manganese may be worked cold or hot ; E. F. Sperry said alloys with up to 30 per cent. manganese can be worked cold or hot ; but E. A. Lewis stated that they can be worked only when hot. L. Guillet found that alloys with up to 40 per cent. of manganese can be rolled. L. Weiller added that alloys with 8 per cent. of manganese can be rolled, but with 12 to 15 per cent. the alloys are brittle. C. Heusler, A. Valenciennes, and J. F. Allen made observations on this subject. Z. Nishiyama's results for the elastic constants are indicated above. According to C. Heusler the tensile strength of the alloys varies from 26 to 41 kgrms. per sq. mm. ; the elastic limit is 15 to 20 kgrms. per sq. mm. ; and the elongation 19 to 29 per cent. E. A. Lewis added that the tensile strength of copper can be increased 26 per cent. by the addition of manganese, whilst the elongation gradually approaches zero as the proportion of manganese is increased to 32 per cent. Observations were also made by E. F. Sperry, A. K. Huntington, E. F. Law, F. W. Webb, A. Schulz, W. B. Parker, and E. le Blant. According to M. Rudeloff, the effect of temp. on an alloy with 5 to 6 per cent. of manganese is not very marked, being :

	15°	100°	200°	300°	400°
Tensile strength .	35·9	35·6	35·7	33·5	25·9 kgrms. per sq. mm.
Elongation .	40·0	32·4	36·5	37·1	23·7 per cent.
Contraction	72·7	60·2	52·4	51·9	— per cent.

A. Valenciennes found that alloys with 3 to 20 per cent. of manganese are as sonorous as bronze. A. Eucken and K. Dittrich discussed the thermal conductivity. A. W. Smith gave for the thermal conductivity k cals. per second per cm. cube at 59°, and the electrical conductivity in mhos $\times 10^{-4}$ at 23° :

Cu .	. 100	90	80	70	60	40	20 per cent.
Thermal	. 0·918	0·065	0·041	0·032	0·031	0·027	0·025
Electrical	. 50·8	2·76	1·59	1·11	0·916	0·820	0·687

K. Dittrich studied the Wiedemann and Franz's conductivity law—**3.** 21, 5—for copper-manganese alloys. K. Feussner and S. Lindeck found that the electrical conductivity curve has a flat minimum with about 33 at. per cent. of manganese. The electrical resistance, R microhms per cm. cube, and the temp. coeff. of the alloys are :

Mn	. 3·5	4·4	6·25	7·8	12·3	24·95	30·0 per cent.
R	. 14·99	17·56	23·61	28·43	43·0	81·2	107·3
a	. 0·0$_3$222	0·0$_3$185	0·0$_4$75	0·0$_4$26	—	0·0$_5$5	0·0$_5$18

The resistance of alloys with 3·5 to 6·25 per cent. Mn increases linearly with temp. and with a higher proportion of manganese attains a maximum at 40° to 60°. The conductivity of an alloy with 22 per cent. of manganese was found by E. F. Sperry to be 3·89 per cent. of that of hard-drawn copper. S. Kimuri and K. Sakamaki, and S. F. Schemtschuschny and co-workers discussed the electrical resistance of the alloys. S. F. Schemtschuschny and W. Petraschewitsch represented the sp. resistance, R ohms, of alloys with :

Copper .	. 100	95·5	79·5	57·5	33·5	10·1	3 at. per cent.
$R \times 10^6 \begin{cases} 25° \\ 100° \end{cases}$.	1·81 2·32	15·56 15·80	59·15 59·15	118·0 118·2	135·8 139·1	104·1 118·1	92 114·5

W. Guertler gave for the ratio of the resistance at $\theta°$ to that at 0° the results indicated in Fig. 17. For a 12·3 per cent. alloy, the temp. coeff. is positive above and negative below 40°. G. Tammann and E. Vaders observed no sharp limiting concentration for the action of reagents on the copper-manganese alloys, but the potential showed a sudden change at the concentration 0·5 mol Cu, and the decomposition potential of the element Cu | MnCl$_2$ | Mn$_n$Cu$_{1-n}$ is independent of the composition of the alloy when $n < 5$; with $n > 5$ it decreases with decreasing amount of copper to zero. M. G. Corson made alloys resistant to inorganic acids by alloying copper with 35 to 55 per cent. manganese. O. Bauer and H. Arndt found an alloy of 66·7 per cent. of copper is not attacked by sulphur at 400° even after 5 hrs., whereas copper alone loses 2 grms. per sq. dm. in the same time. The thermoelectric force was found by K. Feussner and S. Lindeck to have a small negative value against copper, and with alloys

FIG. 17.—The Electrical Resistance at Different Temperatures.

with 12·3, 24·95, and 30·0 per cent. manganese to be respectively —1·4, —2·4, and —3·2 microvolts per degree. R. Sahmen observed that none of the alloys is magnetizable at ordinary temp. S. Kimura and Z. Isawa, and A. L. Norbury discussed the thermoelectric properties of solid soln. of copper and manganese.

K. Ihde found that the magnetic susceptibilities, χ, of a copper alloy with 30 per cent. manganese, and of powdered manganese with a field strength of H gauss, are :

H . . .	1000	2000	3000	4000	5000	5500
$\chi \times 10^{-6}$ { Mn .	101·5	90·6	84·0	79·1	74·6	73·6
{ Mn–Cu .	325	370	359	349	339	336

G. Eger studied the magnetic properties of the alloys, and H. Endo found the susceptibility of the alloys gave a maximum with 70 to 80 per cent. of copper corresponding with the minimum on the f.p. curve.

Copper .	0	20	50	60	70	80	90	100 per cent.
$\chi \times 10^{-6}$.	10·60	13·45	18·96	24·96	34·38	38·18	21·34	0·084

According to A. Valenciennes, an alloy with 15 per cent. of manganese remains unchanged when exposed to air, while E. A. Lewis found that alloys with 70 to 80 per cent. of manganese disintegrate to powder in a few weeks, but not so with the 90 per cent. alloys. According to S. F. Schemtschuschny and co-workers, the peculiar smell emitted by 78 to 100 per cent. manganese, observed by S. Wologdine, occurs only when traces of carbide are present in the metal. G. Tammann and H. Bredemeier discussed the oxide colour films. A. Carnot found that sea-water does not attack alloys with small proportions of manganese. S. Wologdine found that iodine scarcely affects the $CuMn_4$-alloy, but it blackens all the other alloys. A. R. von Schrötter observed that an 18 per cent. alloy is easily dissolved by nitric acid, while it is but little attacked by boiling sulphuric acid, diluted with twice its vol. of water, by hydrochloric acid, or by mercury. R. Sahmen said that alloys with 0 to 35 per cent. manganese are attacked by nitric acid, but not by dil. sulphuric acid. E. Griffiths and F. H. Schofield studied the thermal and electrical conductivities of some alloys ; and A. W. Smith, the electrical conductivity. S. F. Schemtschuschny and co-workers found that the alloys are attacked by a mixture of ferric chloride and hydrochloric acid more easily the higher the proportion of contained manganese. C. S. Smith studied the **copper-manganese-silicon alloys.**

E. Pannain [2] found that **silver-manganese alloys** are formed with difficulty, but if a third metal—e.g. copper—is present, alloys are more easily formed. The alloys were also prepared by P. Siebe. According to G. Hindrichs, silver and manganese form immiscible liquids with between 30 and 88 per cent. manganese. No solid
FIG. 18.—Freezing-Point Curves of the System : Mn–Ag.
FIG. 19.—Freezing-Point Curve of the System : Mn–Ag.
FIG. 20.—Electromotive Force of Mn–Ag-Alloys.

soln. are formed. On the other hand, G. Arrivant found evidence of the existence of **silver hemimanganeside,** $MnAg_2$, and said that this compound forms a continuous series of mixed crystals with silver (Fig. 18), and its limit of miscibility, in the liquid state, with manganese is about 30 per cent. Mn. This is borne out by the microstructure, and by the e.m.f. of such mixtures against a silver electrode.

If the alloys rich in manganese be treated with dil. acids, and the residue be rubbed up with 10 per cent. hydrochloric acid, the hemimanganeside is formed of sp. gr. 8·81 at 0°. When pounded in an agate mortar, it splits into plates. It is stable in air, and reacts with acids like silver. Alloys with up to 20 per cent. of manganese appear homogeneous under the microscope ; and after etching with nitric acid appear corroded like silver ; alloys with a higher proportion of manganese when treated similarly show dendritic crystallization. Alloys with more than 35 per cent. of silver separate into two layers. Alloys with over 90 per cent. of manganese are very brittle. W. Schmidt, and M. Hansen and G. Sachs measured the electrical conductivity of alloys of silver and manganese. The e.m.f. of a silver electrode, depolarized by manganese dioxide, in contact with 10 per cent. of a soln. of manganese sulphate is :

Mn	.	0	2·5	6·0	20·15	29	40	60	80	100 per cent.
Millivolts		16	90	150	250	540	, 490	610	635	630

There is a drop in the conductivity of alloys with between 23 and 20 per cent. of manganese corresponding with the formation of the hemimanganeside (Fig. 20), and again from 20 to 0 per cent. of manganese as a solid soln. is formed. P. Siebe studied the action of chemical reagents on these alloys. F. Saeftel and G. Sachs studied some alloys rich in silver. G. Tammann and E. Vaders observed a limit for the action of chemical reagents on silver-manganese alloys when the mol. proportion of silver is 0·75. L. Jordan and co-workers studied the tarnish resistance of these alloys. M. Keinert studied the **copper-silver-manganese alloys.**

The **gold-manganese alloys** were first investigated by W. C. Roberts-Austen,[3] and F. Osmond. N. Parravano examined the thermal diagram and reported that manganese dissolves in the solid state in gold in proportions up to 10·5 per cent., and gold in manganese up to about 25 per cent. A sharp maximum occurs at **gold manganeside, AuMn,** this compound being capable of dissolving either gold or manganese in the solid state. A liquid miscibility gap occurs between 50 per cent. and 57·5 per cent. of manganese, and certain complex transformations, the nature of which has not been determined, take place in the solid state. Manganese thus differs markedly in behaviour from iron, cobalt, and nickel, and gold from its homologue, copper. The hardness curve exhibits a minimum in exact correspondence with the maximum of the fusion curve. L. Hahn and S. Kyropoulos obtained rather different results.

FIG. 21.—Freezing-Point Curve of the System : Au–Mn.

They observed a temp. interval during the freezing of even the pure metals amounting to 5° for gold and 17° for manganese. The f.p. curve of the series has a maximum at 50 at. per cent., with minima at 33 and 75 at. per cent. of gold respectively (Fig. 21). The crystals exhibit cores, but form only a single solid soln. They do not become homogeneous on alloying for five hours at 700° or one hour at 1000°. The hardness falls with the addition of gold, reaching a minimum at the first minimum f.p. It then increases slightly up to the maximum on the f.p. curve and then falls regularly. Boiling the alloys with water leads to the formation of manganese dioxide. The same result occurs with 20 per cent. hydrochloric acid, so that chlorine is liberated and gold passes into soln., but is reprecipitated as long as manganese remains. G. Tammann and E. Vaders observed that in the action of chemical reagents there is a sharp limit with 0·50 mol of Au. J. O. Linde studied the electrical resistance of the alloys.

H. N. Warren [4] reported a **calcium-manganese alloy** to be formed by heating manganese oxide with calcium carbide, but H. Moissan obtained manganese tritacarbide in the electric furnace from manganese oxide and calcium carbide. Accord-
ing to A. Terreil,[5] a **magnesium-manganese alloy** is formed when magnesium is heated with anhydrous manganese chloride. It is not so hard as the manganese-aluminium alloy. W. Schmidt found that manganese alloys with magnesium, up to about 4 per cent. of manganese forming intermetallic compounds. H. E. Bakken and V. Wood reported that the alloys are solid soln. when at least 3·20 per cent. of manganese is present; J. A. Gaun found that while some manganese is present as solid soln., most of it is in the elementary state as small bluish-grey particles scattered through the crystals of magnesium; and G. W. Pearson showed that the solid soln. extend beyond 2·7 per cent. of manganese, and, in the higher ranges, that metal may show up as angular masses, and in the still higher ranges (35 to 100 per cent. manganese) it appears as irregular masses in a background of magnesium. E. Schmid and G. Siebel found that the solubility curve drops from 3·4 per cent. with the eutectic at 645° to zero at 200°. The lattice constants of alloys with 2·5 per cent. of manganese were measured.

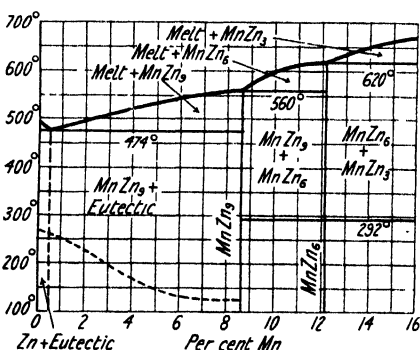
E. A. Lewis prepared some **zinc-manganese alloys**. According to P. Siebe, alloys of zinc and manganese can be prepared containing only up to 50 per cent. of zinc (Fig. 22). Those containing 0 to 11 per cent. of manganese show an arrest at 416°, the eutectic point. The eutectic compound contains a very small, undetermined quantity of manganese, which lowers the m.p. of zinc 3°. The mixed
FIG. 22.—Freezing-Point Curve in the System : Mn–Zn.


FIG. 23.—Portion of Equilibrium Diagram of the System : Mn–Zn.

crystal constituent of the eutectic contains 11 per cent. of manganese, and a series of mixed crystals is formed containing up to 50 per cent. of manganese. The alloys are brittle and increase in hardness as the manganese content increases. C. L. Ackermann gave 414° with 0·4 to 0·5 per cent. manganese for the eutectic. N. Parravano and U. Perret reported that the thermal diagram shows two compounds, **manganese trizincide**, $MnZn_3$, and *manganese heptazincide*, $MnZn_7$. He added that the alloys with 1 to 30 per cent. Mn are hard and brittle; and those with 5 to 20 per cent. manganese are porous. The work of C. L. Ackermann on this subject is summarized in Fig. 22; and observations were also made by P. Gieren. W. N. Pierce said that the eutectic $MnZn_7 + Zn$ occurs with 0·9 per cent. manganese. The heptazincide of N. Parravano and U. Perret is considered to be **manganese hexazincide**, $MnZn_6$, and the temp. zone of its existence is shown in Fig. 23; it melts at 620°. There is also formed **manganese enneazincide**, $MnZn_9$, melting at 560°. These two compounds are totally immiscible with each other in the solid state, but below about 290° alloys containing both compounds undergo some sort of transformation, possibly associated with a reaction between the two compounds or with their decomposition into $MnZn_3$ and zinc. Manganese increases the hardness of zinc considerably, the alloy with 5 per cent. Mn having a Brinell number of 122; at the same time the tensile strength is appreciably increased, whereas the compression strength is much reduced. N. Parravano and

co-workers observed that with alloys with up to 23·3 per cent. Mn there are three phases : (i) a solid soln. of manganese in zinc, the η-phase, with a hexagonal lattice similar to that of zinc and having up to 0·98 per cent. Mn ; (ii) an ϵ-phase with a hexagonal lattice different from that of zinc, and corresponding with $MnZn_7$— 16 atoms per unit lattice ; and (iii) a γ-phase having a body-centred lattice corresponding with $MnZn_3$—48 atoms per unit lattice. C. L. Ackermann found Brinell's hardness of alloys with 0, 0·50, 1·0, 2·2, and 5·0 per cent. of manganese to be, respectively, 53·5, 74·5, 88, 90·5, and 121. The results for the impact, with a load of 4900 kgrms., falling from a height of 40 cms., such that the specific impact energy is 111 cms. per kgrm. per c.c., are shown in Fig. 24 ; the compression results are shown by the dotted lines in Fig. 24. Small quantities of manganese improve the resistance of zinc to repeated impacts, but more than 3 per cent. Mn has the reverse

FIG. 24.—Compression and Impact Tests of the Zinc-Manganese Alloys.

effect. Alloys with up to 8·5 per cent. Mn have a negative potential against zinc in N-zinc sulphate soln. ; those containing the compound $MnZn_9$ have a small positive potential and those containing $MnZn_6$ a much smaller positive potential under the same conditions, whereas the potential of $MnZn_9$ itself is equal to that of pure zinc. The electrode potentials, E volts at 20°, were :

Mn	.	0·4	1·0	6·35	8·50	8·60	10·70	12·50	13·70	16·70
E	.	−5	−6	−6	0	+6	+6	+6	+2	+2

O. Heusler studied the ternary system, the **copper-zinc-manganese alloys,** with less than 50 per cent. manganese. On reference to the copper-zinc binary equilibrium diagram, there are phases with the α-, β-, γ-, δ-, ϵ-, and η-solid soln. The ranges of composition of the phases are indicated in Fig. 25. O. Heusler also studied the effect of annealing at 340° ; and some isothermal melting-points are

FIG. 25.—Phases in the Ternary System : Cu–Zn–Mn.

FIG. 26.—The Ternary System : Cu–Zn–Mn.

represented by the broken lines. O. Heusler observed that feebly diamagnetic brass becomes ferromagnetic when it is alloyed with manganese. The strongest ferromagnetism was exhibited by the alloy with 22 per cent. Cu, 22 per cent. Mn, and 56 per cent. Zn. The zone $CudR_1LCu$, Fig. 26, includes ternary α-solid soln. rich in copper ; dMR_3R_1d, α- and β-solid soln. ; R_3MeT_2, ternary β-solid soln. ;

$efU_2T_1T_2e$, ternary γ-solid soln., and mixtures with β-solid soln.; fPU_3U_2F, ternary δ-solid soln. and mixtures with γ- and ϵ-solid soln.; and T_3U_3PZni, ternary ϵ- and η-solid soln. with their mixtures. The α- and β-solid soln. were studied by W. Rosenhain and F. C. A. H. Lantsberry, and O. Heusler.

G. Tammann and J. Hinnüber [6] found the solubility of manganese in mercury to be 2.5×10^{-4} per cent. N. M. Irvin and A. S. Russell gave 0·001 per 100 grms. of mercury. According to R. Böttger, when sodium amalgam is placed in a conc. soln. of manganese sulphate, hydrogen is evolved, and manganous oxide is formed, but under a conc. soln. of manganous chloride some **manganese amalgam** is formed. C. F. Schönbein, W. B. Giles, J. Schumann, and H. Moissan also obtained the amalgam in an analogous manner. W. Ramsay, J. Schumann, H. Moissan, E. Kuh, A. N. Campbell, and O. Prelinger also prepared the amalgam by the electrolysis of soln. of manganous chloride with a mercury cathode. A. Guntz squeezed the product between leather and then between paper to get rid of the excess of mercury. The amalgam is silvery-white and more or less viscid. It can be obtained in needle-like crystals. O. Prelinger said that the excess of mercury is squeezed from the amalgam in Swedish leather, between two pieces of hard wood, under a press. of 2000 kgrms. per sq. cm.; the peripheral portion of the pressed cake is broken off and the central portion broken up and again compressed. The operation is repeated until pieces punched from the centres of successive discs have the same composition. The residue has the composition of *manganese hemipentamercuride*, Mn_2Hg_5, and a sp. gr. 12·823. This product has a slate-grey colour, and assumes a metallic lustre when rubbed or cut. At ordinary temp. it oxidizes very slowly in the air, metallic mercury being eliminated. At 100° to 110° it decomposes slowly into its elements. It decomposes water and acids at the ordinary temp. Manganese amalgam is electro-positive to manganese, so that heat is probably absorbed in its formation. A solution of the compound in mercury is not attacked by dry air, but is quickly oxidized by moist air to manganic oxide, Mn_2O_3, which forms a fine dust on the surface of the liquid. E. Kuh found that the ordinary amalgam is stable when confined in a vacuum desiccator over calcium chloride; but in air it is the more stable the smaller the excess of mercury it contains. W. B. Giles added that the amalgam acquires a brown skin when exposed to air, forming, said J. Schumann, powdered manganese oxide and mercury. W. Ramsay found the mol. wt. of manganese to be 112·4 when calculated from the lowering of the vap. press. of mercury by manganese. C. F. Schönbein found that when the amalgam is shaken with air and acidulated water, some hydrogen dioxide is formed. The amalgam is slowly decomposed by water, and, according to W. Ramsay, it is decomposed by alcohol. According to R. Böttger, water or dil. acids may form some hydrogen. O. Prelinger found that when heated in hydrogen, mercury is vaporized, and manganese powder remains; with nitrogen, manganese nitride is formed with incandescence. According to A. S. Russell and co-workers, the order zinc, cadmium, manganese, thallium, tin, lead, copper, chromium, iron, bismuth, cobalt, and nickel is the order of removal of these metals from their amalgams by an oxidizing agent; and their positions in the potential series are Cr, Mn, Fe, Co, Ni.

C. and A. Tissier [7] reported that manganese oxide is not reduced in a dry way by aluminium, but something must have gone wrong, for reduction readily occurs in the alumino-thermite process. L. Guillet prepared the **aluminium-manganese alloys** by this process, and C. Combes, by heating aluminium with manganese sulphide or chloride. A. J. Bradley and P. Jones observed, by means of the X-radiograms, seven different phases in the Mn-Al alloys: (i) $Al + Al_7Mn$; (ii) Al_7Mn and Al_3Mn; (iii) Al_3Mn and a solid soln. extending over 50 to over 59 per cent. Mn; (iv) a phase with this solid soln. and a phase with the β-form of manganese; (v) a phase with the β-form of manganese, alone, and (vi) with the β- and α-forms; and (vii) a phase with α-manganese. S. Daniels studied alloys with up to 9·6 per cent. of manganese. He observed that the tensile strength was raised from 5·25 tons per sq.

in. for the alloy containing no manganese to 7·6 tons per sq. in. with 1·02 per cent. Mn, but the elongation (on 2 ins.) fell rapidly from 38·5 per cent. to 22·6 per cent. and then to 2·6 per cent. with no manganese, 1·02 per cent., and 2·88 per cent. Mn respectively. The Brinell hardness numbers gradually increased from 20 to 48 with increasing manganese content. E. Ludwik found that Brinell's hardness of some binary aluminium alloys could be represented by $H = a + b \log P_v$, where a is a constant dependent on the nature of the other component; b is a constant; P_v the vol. per cent. of the compound of the added metal; and H is the depth the ball sinks expressed in μ. K. Röth found that for aluminium-manganese alloys, when the compound Al_3Mn is present, $H = 568 - 200 \log P_v$, and

Mn	.	0·5	0·8	1·6	2·4	4·4	7·6	7·9	10·0 per cent.
P_v	.	0·4	0·7	1·5	2·2	4·1	7·2	7·8	10·0
H .	.	648	605	528	500	460	396	400	384μ

S. Daniels found that the presence of manganese increased the shrinkage and promoted porosity when present in appreciable quantity. The alloy containing 4·6 per cent. of manganese machined like cast-iron, probably owing to the presence of the hard and brittle compound $MnAl_2$. The alloys were readily attacked by distilled water during 30 days' immersion, but showed only a slight corrosion after 100 hrs. in salt spray. Heat treatment at 580° for 96 hrs., followed by quenching in water and ageing at 149° for 2 hrs., did not materially alter either the physical or mechanical properties or the corrodibility.

D. J. McAdam observed that the simultaneous action of corrosion and fatigue—corrosion-fatigue—may cause failure at stresses far below the ordinary endurance limit—*vide* the corrosion of iron. With an aluminium-manganese alloy containing 97·98 per cent. of aluminium and 1·22 per cent. of manganese, the static mechanical tests were :

	Tensile strength (lbs. per sq. in.)	Elastic limit (lbs. per sq. in.)	Proportional limit (lbs. per sq in.)	Elongated (per cent. in 2 ins)	Reduction of area (per cent.)
Hard . .	29,600	13,300	11,500	12·3	46·3
Half-annealed	23,800	13,000	9,300	19·7	57·3
Annealed .	16,700	2,200	1,900	64·2	70·3

The corrosion-fatigue graphs represent the stresses and the logarithms of the number of cycles for specimens tested in air (fatigue curve), in a corroding fresh carbonate water, and in a corroding river salt-water having about one-third the
FIGS. 27, 28, and 29.—The Fatigue and Corrosion-Fatigue of Manganese-Aluminium Alloys.

saline contents of sea-water, and with cycles of 1450 revs. per minute. The results shown in Figs. 27, 28, and 29 refer to the 1·22 per cent. manganese alloy in the three states just indicated—namely, hard, medium, and soft. C. S. Taylor and J. D. Edwards studied the thermoelectric force of the alloys.

P

S. Daniels also studied the metallography or microstructure ; and Z. Nishiyama, and A. Westgren and W. Ekman, the X-radiograms of these alloys. G. Hindrichs studied the f.p. of the Al–Mn-system, Fig. 30, and found that alloys containing between 57 and 86 per cent. of aluminium separate into two liquid layers ; and that there are indications of the formation of the two compounds MnAl$_3$, and Mn$_3$Al. T. Ishiwara's results are summarized in Fig. 31, and the curve corresponds in the main with that of G. Hindrichs, but the results are interpreted differently in some respects. There is a maximum B in the f.p. curve $A'JCBM'$ corresponding with the formation of the aluminium tritamanganeside, Al$_3$Mn. At the horizontal line
FIGS. 30 and 31.—Freezing-Point Curve of the System : Mn–Al.

FGH there is a reaction between the liquid F and the compound Al$_3$Mn resulting in the formation of **aluminium pentitamanganeside,** Al$_5$Mn. At the temp. corresponding with OPQ there is a peritectoid reaction in the solid alloy resulting in the formation of a solid soln., Pa, from the solid soln. $O\gamma$ and the solid Q or β-Mn ; and at the temp. TV there is an eutectoid reaction between solid soln. $U\gamma$ and $T\delta$ resulting in the formation of the solid soln. Va. Manganese exists in three allotropic forms a, β, and γ. E. H. Dix and W. D. Keith studied the aluminium end of the system. Observations were also made by H. Schirmeister, and E. Bassow. L. Guillet said that the alloys with a high proportion of manganese are very stable in air, but those with Al : Mn=1 : 2 and 1 : 5 easily disintegrate, and contain *aluminium tritadimanganeside*, Mn$_2$Al$_3$. He also said that there are probably **aluminium tetritamanganeside,** Al$_4$Mn, and **aluminium tritamanganeside,** Al$_3$Mn. The conditions of equilibrium of the tritamanganeside are indicated in Fig. 31. F. R. Michel prepared this compound by melting ten parts of a mixture of manganous chloride and sodium chloride with 5 parts of aluminium and 20 parts of a mixture of sodium and potassium chlorides, and then melting the regulus with 8 parts of aluminium under a flux of the alkali chloride, and removing the excess of aluminium by very dil. hydrochloric acid. Acicular crystals and quadratic prisms remain. The sp. gr. is 3·402. The compound

FIG. 32.—Melting-Points of Ternary Mixtures : Mn–Al–Cu.

is not soluble in cold, dil. or conc. nitric acid, but it dissolves in the hot acid. The compound is soluble in hydrochloric acid, and in dil. sulphuric acid ; but with hot, conc. sulphuric acid some sulphur separates out. The compound decomposes water at 100° ; with boiling, conc., aq. ammonia, hydrogen is evolved ; and with dil. soda-lye the aluminium is dissolved, and oxidized manganese remains. W. Haas said that alloys of aluminium with manganese—say 2 per cent.—resist corrosion by sea-water better than the common aluminium alloys. D. J. McAdam studied this subject. O. Brunck reported Mn$_2$Al$_7$—possibly MnAl$_3$—to be formed by melting a mixture of manganese with six times its weight of aluminium under

a layer of sodium chloride, and treating the crystalline regulus with 2 per cent. hydrochloric acid. The tin-white crystals are soluble in conc. hydrochloric acid. The conditions of equilibrium of **aluminium trimanganeside,** $AlMn_3$, are indicated in Fig. 31. A. Terreil obtained it by reducing manganous chloride with aluminium. It scratches glass, and the fracture recalls that of amalgamated zinc. W. Krings and W. Ostmann could not confirm the existence of aluminium tritamanganeside, but they obtained the tetritamanganeside. In the ternary system, Al–Mn–Cu, Fig. 32, there is a ternary eutectic with 29·6 per cent. of copper, 3 per cent. of manganese, and 67·4 per cent. of aluminium, at 536°. There is an area of ternary mixed crystals and a polyphase area, but no evidence of a ternary compound. If less than 45 per cent. of copper is present, two liquid layers are formed. S. F. Herman and F. T. Sisco, R. L. Templin and D. A. Paul, and E. T. Richards studied the elastic properties of the alloys.

About 1901, F. Heusler accidentally discovered that the turnings of a manganese alloy were magnetic; and F. Heusler and co-workers observed that a copper-manganese alloy itself is non-magnetic, but when associated with a third element—zinc, tin, arsenic, antimony, bismuth, or boron—the alloy becomes more or less magnetic, and in the case of aluminium a good ferromagnetic alloy is produced, for it is strongly attracted by the poles of a magnet and it is capable of retaining permanent magnetism. Some binary compounds—e.g. manganese boride, arsenide, antimonide, and bismuthide (q.v.)—were also found to be magnetic to a less degree. The more important ternary alloys are those in which aluminium is the third component, and these are usually understood by the term **Heusler's alloys.** The best results are obtained with alloys containing approximately atomic proportions of these elements, namely, 62·5 per cent. Cu, 25 per cent. Mn, and 12·5 per cent. Al—Fig. 33. As the proportion of copper is reduced, the magnetic quality improves, but if less than 60 per cent. of copper be present, the alloy is too hard and brittle to be worked on a lathe. H. H. Potter studied the effect of magnetization on the electrical resistance, and also the magneto-caloric effect of these alloys.

L. Harang found that the ternary alloys of aluminium, manganese, and copper show three cubic lattices : (i) a face-centred one of varying size ; (ii) a body-centred one, with $a = 2\cdot975$ A., of manganese and aluminium ; and (iii) a simple cubic lattice, with $a = 8\cdot71$ A., of aluminium and copper. E. Persson also discussed this subject. J. F. T. Young observed a face-centred cubic lattice with $a = 3\cdot70$ A., and a body-centred lattice with $a = 2\cdot98$ A. This agrees with the assumption that the alloys are solid soln. of a manganese-aluminium alloy in copper. The subject was studied by H. O. Dorum. H. H. Potter found that the alloy crystallizes as a body-centred lattice with $a = 2\cdot95$ A. ; that the aluminium atoms are distributed on a face-centred cube with $a = 5\cdot9$ A. The directional magnetic properties are the same

FIG. 33.—The Intensity of Magnetization of some Cu–Mn–Al Alloys.

as those of nickel, which has a face-centred cubic lattice. It is probable that the manganese atoms lie on a face-centred cubic lattice. E. Persson's X-radiograms of the Cu–Mn–Al alloys show that the magnetism is definitely associated with the crystalline structure denoted by the β-phase. This consists of a body-centred cubic lattice, with the Al atoms so distributed as to form a face-centred cubic superstructure. This crystalline form is magnetizable only when the Mn content exceeds a certain minimum value corresponding with $(Cu,Mn)_3Al$. The lattice parameter of the β-phase in quenched alloys increases with increasing manganese
content.   The highest manganese content in the β-phase corresponds with maximum magnetizability.   In tempered alloys the β-phase is resolved into two crystalline forms of similar structure—one is a β-Cu-Al phase free from manganese, and the other a β-phase with the maximum manganese concentration corresponding with CuMnAl, and called the β'-phase.   The simultaneous occurrence of the two phases is taken to mean that their crystalline forms are different.   The β'-phase is considered to be characterized by a twofold superstructure, in which one of its four face-centred lattices is probably composed chiefly of Al-atoms, another chiefly of Mn-atoms, and the two remaining ones almost exclusively Cu-atoms.   All the alloys with the β'-phase are ferromagnetic, and this agrees with an observation of H. H. Potter to the effect that the ferromagnetism of the Heusler alloys is intimately connected with the orientation of the Mn-atoms in the face-centred structure.   When a (Cu,Mn)Al-phase appears with the higher concentrations of aluminium, the alloy is non-magnetic.   Unlike A. Kussmann and B. Scharnoff, S. Valentiner and G. Becker infer that the magnetic properties cannot be referred to any definite lattice or phase ingredient.

According to A. A. Knowlton, there is no simple relation between composition and magnetic properties.   The alloys showed no sign of recalescence; the critical temp. for one specimen was 0° and for another 200°.   The microstructure shows three types of crystals: (1) bright ones, unaffected by the etching fluid (HCl and $FeCl_3$); (2) dark ones, deeply etched; and (3) yellowish ones of the nature of a matrix.   Crystals of the first type were evidently the magnetic ones, as no specimen from which these were absent was magnetic, and the value of the intensity of magnetization, I, could be estimated with a fair degree of approximation from the area of these crystals.   E. B. Stephenson also examined the microstructure of these alloys.   The microstructure varies greatly with the heat treatment.   The variations in the electrical conductivity and hardness with the age of the alloys were studied by F. Heusler and E. Dönnges.   G. A. Shakespear examined the expansion effect between 250° and 300°.   A. Rosenheim and co-workers, and E. Morlet studied the mechanical properties of the alloys.   E. Morlet studied the effect of manganese on the hardness of the copper-aluminium alloys; and G. Masing, the age-hardening of the alloys.   P. W. Bridgman found for the alloy *therlo*—Cu, 85; Mn, 13; Al, 2—the cubic compressibility 0.7×10^{-6}; the reciprocal of Young's modulus, 0.69×10^{-6}; and Poisson's ratio, 0.33.

FIG. 34.—The Effect of Temperature on the Specific Heat, Magnetic Induction, and the Rate of Change of the Magnetic Induction with Temperature.

E. Dippel found the sp. ht. of an alloy slowly cooled was 0.10589, and that of an alloy heated to 600° and rapidly chilled, 0.10709. W. Sucksmith and H. H. Potter found that the sp. ht. curve, Fig. 34, changes rapidly near the critical temp., about 280°, showing that heat is rapidly absorbed as the substance changes from a ferro-magnetic to a paramagnetic state.   J. R. Ashworth studied the relations between the thermal and magnetic constants.

S. Fabiani found for the alloy Cu : Mn : Al=58·9 : 26·5 : 14·6, the absorption coeff. k, and the index of refraction μ, for light of wave-length λ :

λ	.	.	4970	5440	5893	6380	7070
k	.	.	2·92	3·18	3·42	3·65	3.93
μ	.	.	1·90	2·08	2·24	2·39	2·28

J. C. McLennan and co-workers gave 725 for the resistance, R microhms, of Heusler's alloy at 27°; 696 at 0°; 311 at —88°; 208 at —268·8°; and 203 at —271°. P. W. Bridgman observed that the resistance of the alloy *therlo*—Cu, 85 ; Mn, 13 ; Al, 2—taking unity at 0°, is 1·00120 at 50°, and 1·00104 at 100°. The press. coeff. at 0 and 12,000 kgrms. press. per sq. cm. are respectively 0·0₅2361 and 0·0₅2273 at 0°; 0·0₅2386 and 0·0₅2318 at 50°; and 0·0₅2367 and 0·0₅2320 at 100°. The resistance passes through a maximum between 0° and 75°. When under tension, the resistance changes in accord with the tension coeff., —0·0₆73. The magnetic induction curve, I, and the curve showing the rate of change of the magnetic induction with temp., $dI|dT$, are also shown in Fig. 34. The results show that the magnetic and thermal phenomena are intimately connected, and that the magnetic change is associated with a heat of transformation. W. Preusser's observations on the intensity of magnetization, I, of the ternary alloys of different composition are shown in Fig. 35. F. Heusler and F. Richarz showed that forged copper alloys with 20 per cent. or less manganese and 6 per cent. aluminium are entirely non-magnetic when quenched from a red-heat in water or mercury, but after heating for several hours in boiling xylene, a maximum degree of magnetizability is reached, and the alloy is found to be free from hysteresis. The same alloys, slowly cooled, show hysteresis, which is the greater the slower the cooling through the critical range. The magnetic susceptibility decreases rapidly with an increase in the proportion of aluminium. The maximum susceptibility is obtained when the alloys have the composition AlM₃, where M represents manganese and copper, which replace one another isomorphously in the compound. In this isomorphous series the magnetic susceptibility increases with increasing manganese, and a maximum should be reached by the compound AlMn₃, which is to be examined for its magnetic properties. A. Kussmann and B. Scharnoff traced the anomalies to a change of phase in the neighbourhood of 130°. J. A. Fleming and R. Hadfield found that the curves representing the remanence, B, and the intensity, H, of the magnetic field are similar to those for cast-iron. An alloy with 61·68 Cu, 22·57 Mn, 13·63 Al, and 1·51 Pb gave E. B. Stephenson the results shown

FIG. 35.—The Magnetic Induction and Intensity of the Magnetic Field.

in Fig. 35. The saturation intensity is about one-fourth that of iron. According to A. A. Knowlton, the critical range of temp. of magnetic transformation is from 250° to 450° according to the composition. The change from the magnetic state occurs over this range of temp. If the alloy be quenched 50° to 100° above the upper limit, it is almost non-magnetic, but if the temp. be now raised to 120°, maintained there for some hours, and then cooled slowly, the magnetic property reappears. This tempering brings about favourable changes which at ordinary temp. would require a year or more of ageing. A. D. Ross found that quenching from still higher temp. greatly reduces the magnetic hysteresis and the coercive force is about one-sixth that of soft iron. The loss of magnetic susceptibility which results from quenching may be restored by ageing at 120°, but the low coercive force persists, so that the alloys may be used for replacing iron in iron-cored electromagnetic instruments. At the temp. of liquid air the permeability in fields up to 200 C.G.S. units may be 25 per cent. greater than at ordinary temp. An alloy made feebly magnetic by quenching from a high temp. has its magnetism largely restored on cooling to 190°, although the improvement is not maintained on returning to the ordinary temp. According to W. Krings and W. Ostmann, the maximum susceptibility of Heusler's alloys lies at the point of intersection of Cu₃Al and AlMn₃. Alloys containing more than 30 per cent. of manganese, which have not been previously investigated, are also magnetic. The increase and decrease of magnetic properties are accompanied by changes of structure. In contradistinction to Heusler's alloys, which attain their maximum magnetic susceptibility after being
heated at 144° for a long period, alloys of high manganese content exhibit their maximum magnetic properties after ageing at a high temp., whereas ageing at 144° causes all magnetic effects to vanish. The magnetostriction was studied by L. W. Austin, K. E. Guthe and L. W. Austin, and J. C. McLennan; K. E. Guthe and L. W. Austin tested samples for the modulus of elasticity; H. Zahn and H. Schmidt found the coeff. R for the Hall effect is 1300×10^{-5}, and that the coeff. Q for the thermomagnetic effect is -500×10^{-6}.

The magnetic properties of the alloys were also studied by B. V. Hill, A. Gray, H. O. Dorum, etc. B. V. Hill said that the magnetic effect is reversible up to about 375°, but at 500°, irreversible. Many attempts have been made to locate the magnetic unit. J. A. Fleming and R. Hadfield assumed that the magnetic properties of these alloys are due to molecular grouping, and are not characteristic of the elements themselves. F. Heusler, as indicated above, regards the magnetic unit as a complex, $\{Al(Cu,Mn)_3\}_n$. The aluminium and copper in the complex can be replaced isomorphously, or, as A. D. Ross expressed it, solid soln. of Cu_3Al and Mn_3Al may be formed. This leaves it an open question whether the magnetism is to be attributed to the simple molecules, $Al(Cu,Mn)_3$, to complexes, $\{Al(Cu,Mn)_3\}_n$, or to a particular crystal lattice. O. von Auwers and co-workers studied the ageing of the alloys between 100° and 300° required to develop full magnetic power. One effect of this treatment is to raise the magnetic transition temp. along a curve similar to a magnetization curve. When magnetization is plotted against time of ageing for different field strengths, a series of curves is obtained, of which those for lower field strengths show a sharp maximum, with a subsequent fall to a constant magnetization (Fig. 36). In the curves for high field strengths the maximum is flattened out and the corresponding point is followed by a gradual rise in magnetization as the time of ageing increases. The ageing process appears to involve two superimposed molecular changes. At the magnetic transition point, the magnetic particles become dissociated. On quenching from about 600° the alloy contains very few magnetic molecules. By slow cooling or by the ageing process the particles again become associated and the magnetization and coercive force both increase. With low field strengths the coercive force—that is, the intermolecular force—predominates over the magnetizing force, and this explains the maximum in the above-mentioned curves. The highest point of the magnetization curve is reached when the coercive force is a maximum, that is, when the maximum number of magnetic particles are present. The coercive force depends on the temp. of ageing, and reaches a maximum with temp. from 190° to 260°. Above this temp. it falls off rapidly, presumably because the dissociation of the particles has then commenced. L. Harang's X-radiograms did not agree with the assumption that the magnetism is tied up with a complex $(AlM_3)_n$, where M denotes an isomorphous mixture of copper and manganese, for the magnetic character cannot be associated with any single lattice. J. R. Ashworth discussed the temp. coeff. of the resistance and the thermoelectric power; and also the application of an equation of state—vide iron—to these alloys. W. Sucksmith and H. H. Potter compared P. Weiss's theory of the relation between the sp. ht. and the magnetization of these alloys. E. Persson attributed the magnetism of the Cu–Mn–Al alloys to a β-phase, consisting of $(Cu,Mn)_3Al$, which is formed in the quenched alloys, with aluminium in

FIG. 36.—The Intensity of Magnetization for Different Field Strengths with Different Times of Ageing.

solid soln. This phase on annealing breaks up into a β-copper-aluminium phase and the Cu_2MnAl phase with a maximum manganese content. The higher the proportion of manganese: $(Cu,Mn)_3Al$, the stronger the magnetization. J. R. Ashworth discussed the relations of the magnetic and thermal constants. H. H. Potter studied the magnetic properties of the **silver-manganese-aluminium alloys.** P. Hidnert and W. T. Sweeney measured the coeff. of expansion of **magnesium-manganese-aluminium alloys ;** and E. Griffiths and F. H. Schofield, the thermal and electrical conductivities of some aluminium bronzes alloyed with manganese. W. Sucksmith and L. F. Bates found the ratio of the gyromagnetic effect to be $K=0.501$—*vide* the magnetism of iron.

N. Baar [8] found that molten manganese and thallium are almost immiscible at 1200°, but the f.p. of manganese is slightly lowered by the addition of thallium, showing that a **thallium-manganese alloy** is formed—Fig. 37.

C. S. Smith,[9] and E. Voce studied some **copper-silicon-manganese alloys ;** and H. A. Bedworth, the resistance of the alloys to acids. E. Voce represented an approximation to the solid phases in the ternary manganese-silicon-copper alloys by Fig. 38. He measured the mechanical properties of the alloys and the

FIG. 37.—Freezing-Point Curve of the System : Mn–Tl.

results for the annealed alloys are summarized in Figs. 39 to 41, where the curves represent the data in tons per sq. in. He found that copper and silicon-copper resisted conc. sulphuric acid fairly well, but silicon-manganese-copper alloy was moderately attacked. All the metals resisted normal and decinormal sulphuric acid quite well, the rate of attack being from 8 to 13 mgrms. per sq. cm. per month. " Mine water " —*i.e.* normal sulphuric acid containing dissolved sulphates—is three or four times as corrosive as the same acid free from sulphates. Normal and decinormal hydrochloric acid attacked all the alloys to a greater extent than sulphuric acid of the

FIG. 38.—Phases in Chill-Cast Si–Mn–Cu Alloys.

FIG. 39.—Tensile Strength of Annealed Si–Mn–Cu Alloys.

same concentrations, the loss in weight varying from about 30 to 90 mgrms. per sq. cm. per month. As might be expected, normal nitric acid rapidly attacks copper and the silicon alloys. On the other hand, decinormal nitric acid has scarcely more action than sulphuric acid of the same concentration. All the metals showed a fair degree of resistance to normal formic and acetic acids (8–15 mgrms. per sq. cm. per month), and mixing the two acids did not increase the rate of attack. In

synthetic sea-water there was little to choose between the alloys. When the alloys were exposed to air at 725° to 825°, the scale formed on silicon-copper alloys resembled that ordinarily formed on copper, in so far as it consisted of a black cupric oxide layer superimposed upon a firmly adherent cuprous oxide film. In the case of alloys containing appreciable quantities of silicon the cuprous oxide film is buff in colour and contrasts strongly with the red oxide produced on copper. The

FIG. 40.—Percentage Elongation of Annealed Si–Mn–Cu Alloys.
FIG. 41.—Izod Impact Values of Annealed Si–Mn–Cu Alloys.

modification of the colour is probably due to the admixture of silica. The resistance of silicon-copper alloys to high-temperature oxidation in the neighbourhood of 700° increases with the silicon content. At 725° the rate of oxidation of an alloy containing 4·58 per cent. silicon was from one-fourth to one-seventh that of copper. The adherence of the outer layer of black oxide was likewise a function of the silicon content. For the 4·58 per cent. silicon alloy it was very firmly adherent. At temp. above 800° the oxidation rate increases and approximates to that of pure copper. The addition of 1 per cent. manganese to a 4 per cent. silicon alloy did not appreciably alter the rate of oxidation, but rendered the black oxide much less adherent. In 1773, R. Dovey patented the use of " mangonize oar " with alloys of copper, zinc, and tin to produce an alloy " in all respects resembling gold." T. Goldschmidt made **tin and manganese alloys** by the aluminothermite process. According to R. S. Williams, the f.p. curve of these alloys, Fig. 42, has a break at 989°, corresponding with **tin tetramanganeside,** $SnMn_4$, which decomposes below

FIG. 42.—Freezing-Point Curve of the System: Mn–Sn.

its m.p., and not only shows considerable magnetic permeability, but is permanently magnetic. It is fairly hard—hardness on Mohs' scale 4 to 5—it is not so brittle as manganese, and takes a good polish. A second break occurs at 898°, corresponding with **tin dimanganeside,** $SnMn_2$, which decomposes below its m.p. It shows a slight magnetic permeability, and it is softer than the tetramanganeside—hardness 3 to 4—and is less readily attacked by dil. acids. A third break occurs at 541°, and probably corresponds with **tin manganeside,** SnMn. This compound has but a slight magnetic permeability. It decomposes be-

low its m.p. and is silvery-white. A series of mixed crystals extends from about 95 to 100 at. per cent. of manganese. H. H. Potter studied the magnetic properties of $SnMn_4$ and $SnMn_2$; and P. Martin, Kerr's effect. N. A. Puschin measured the potential curve, E millivolt, of $SnMn_n$ against tin in N-KOH, and found :

n	20	50	55	65	73	75·5	75·6	77	84	86	100
E	−10	−4	16	33	44	755	720	890	865	885	930

With 50 at. per cent. of manganese the alloy makes a jump, probably corresponding with the SnMn-compound, and with 75 at. per cent. manganese there is a sharp break, corresponding with SnMn₃. H. Fassbender examined the magnetic properties of the Mn–Sn alloys, and he obtained a maxima on the susceptibility curve corresponding with SnMn₄. F. Heusler studied the magnetic properties of the ternary alloys—tin, manganese, and copper. L. Harang found from the X-radiograms of the ternary alloys of tin, manganese, and copper that a high tin content corresponds with a hexagonal lattice, possibly due to a compound of copper and tin. A. D. Ross and R. C. Gray found that the ternary alloys of copper, manganese, and tin with the 14 to 18 per cent. of tin are more magnetic at −190° than at ordinary temp. The quenching of the ternary alloys from 350° to 580° produces complex changes, the coercive force being always diminished, and the effect cannot be reversed by again annealing. The quenched alloys are more improved in magnetic properties by cooling to −190° than those in the normal condition. Baking at 180° to 200° diminishes the susceptibility and increases the coercive force. F. Heusler found that in these alloys the maximum of magnetic properties is found, in accordance with the general rule, in the alloy in which the sum of the manganese and copper atoms is three times the number of tin atoms. In the aluminium series the maximum is reached at $(AlMnCu_2)_n$. The ferromagnetic quality falls off much more rapidly from the maximum in the tin series than in the aluminium series.

R. S. Williams prepared **lead and manganese alloys** by melting the two elements at about 1500°; and A. Stavenhagen and E. Schuchard, by reducing a mixture of the oxides with aluminium. J. F. Allen also prepared these alloys. R. S. Williams said that fused manganese dissolves 10 per cent. of lead and its m.p. is at the same time lowered from 1228° to 1198°. At the same temp. lead dissolves about 12 per cent. of manganese, but the manganese separates out completely as the temp. falls to the m.p. of lead. The equilibrium diagram is shown in Fig. 43. This subject was also studied by K. Bornemann. The alloys are not magnetizable.

G. Arrivant [10] prepared **molybdenum-manganese alloys** containing 12·25 to 29·64 per cent. Mn by fusing a mixture of the metallic powders at 1500° in a current of hydrogen, and also by reducing a mixture of the oxides by means of aluminium. The alloys are hard and brittle, and are readily soluble in dil. or conc. mineral acids.

FIG. 43.—Freezing-Point Curve of the System : Mn–Pb.

These alloys are said to consist of free manganese associated with **molybdenum hexamanganeside,** Mn_6Mo, which can be separated by means of dil. acetic acid, or ammonium acetate, in dil. alcoholic soln., in which the compound is insoluble. It forms plates of sp. gr. 7·28 at 0°. In a similar manner **molybdenum tetramanganeside,** Mn_4Mo, is produced as a granular powder of sp. gr. 7·62. The compounds are attacked by chlorine, or strong mineral acids at ordinary temp.; by water at 250°; and by alkali carbonates, nitrates, or hydrosulphates at a red-heat. Alloys richer in manganese are obtained by the alumino-thermite process. They are hard, brittle, silver-white, non-magnetic, and readily soluble in hot, conc. nitric or sulphuric acid, or fused alkali hydrosulphate. The alloys consist of manganese associated with one of the three compounds Mn_2Mo, $MnMo_2$, or $MnMo$. When the alloy with 35·11 to 43·94 per cent. Mo is treated with a 10 per cent. alcoholic soln. of acetic acid, **molybdenum dimanganeside,** Mn_2Mo, is left as a steel-grey powder of sp. gr. 8·37 at 0°. By treating alloys with 43·57 to 59·25 per cent. Mo with dil. hydrochloric acid, there remains **molybdenum manganeside,** MoMn, as a steel-grey powder of sp. gr. 8·60 at 0°; and by treating alloys with 64·70 to 72·27 per cent. of Mo with conc. hydrochloric acid, there remains a steel-
grey powder of **molybdenum hemimanganeside**, $MnMo_2$, of sp. gr. 8·70 at 0°. These three compounds are attacked by chlorine at ordinary temp., or with incandescence at 300°, by oxygen or sulphur at a red-heat, and by water-vapour at 250°. Hydrochloric and hydrofluoric acids dissolve only the dimanganeside. W. Guertler and T. Liepus studied the corrodibility of the copper-manganese-molybdenum alloys. J. J. and F. de Elhuyar [11] prepared **manganese and tungsten alloys**; and G. Arrivant prepared alloys containing 12·21 to 60·05 per cent. of tungsten, by reducing with aluminium a mixture of the oxides of the two metals with their respective peroxides ; they form hard, brittle ingots, steel-grey in colour, and non-magnetic. These alloys, which do not contain any definite compounds of the two metals, are slowly oxidized in the air, and completely dissolved by boiling conc. sulphuric acid or by fused alkali hydrogen sulphates ; dil. acids attack them in the cold, dissolving the manganese and leaving the tungsten in the form of a heavy, metallic, steel-grey powder having a sp. gr. 15·28 at 0°. Alloys of tungsten and manganese containing not more than 25 per cent. of the former metal can also be prepared by fusing a mixture of the metallic powders in a current of hydrogen. H. List said that the two elements do not form alloys. A. Stavenhagen and E. Schuchard obtained **uranium-manganese alloys** by the thermite process.

§ 8. Manganous Oxide and Hydroxide

C. W. Blomstrand [1] observed that the emerald-green, cubic crystals occurring in the manganiferous dolomite of Längban, Wermland, Sweden, consist of **manganous oxide**, or **manganese monoxide**, MnO, contaminated with about a half per cent. of iron. He called the mineral **manganosite**. A. Sjögren also found this oxide occurred in the Moss Mine, Nordmask, Wermland, Sweden. The manganese oxides

were studied by R. Phillips in 1829. A. Geuther said that pyrolusite heated to bright redness furnishes the monoxide, but W. Biltz's observations—*vide infra*—show that more probably the manganosic oxide, Mn_3O_4, is formed. C. W. Scheele obtained the monoxide by heating manganous carbonate to redness out of contact with air ; H. Davy, by heating manganous hydroxide ; and J. von Liebig, F. Kessler, J. Bachmann, J. L. Lassaigne, and A. Gorgeu, by heating manganous oxalate. E. G. L. Roberts and E. A. Wraight obtained the monoxide by fusing manganese dioxide in a magnesia-lined crucible ; and E. Tiede and E. Birnbräuer said that the dioxide is reduced to the monoxide when it is heated to 1650° in vacuo. J. A. Arfvedson prepared the monoxide by heating manganous carbonate to redness in a current of hydrogen ; G. Forchhammer, E. Turner, J. N. von Fuchs, E. R. Schneider, and F. Kessler, manganosic oxide ; and C. R. A. Wright and A. P. Luff, and H. Moissan, manganese dioxide. H. Moissan added that the reduction of manganese dioxide by hydrogen occurs at 280°, and of manganosic oxide, prepared at a low temp., at 260°. L. Wöhler and O. Balz found that the equilibrium constant $C_{H_2O}/C_H = K$ in the reaction $Mn_3O_4 + H_2 \rightleftharpoons H_2O + 3MnO$, is 34·6 at 450°. K. Stammer reduced manganosic oxide to manganous oxide by heating it in carbon monoxide. A. Guntz found that manganese and carbon dioxide begin to react : $Mn + CO = MnO + C + 33·3$ Cals. at 350° ; and the reaction with carbon dioxide : $2Mn + CO_2 = 2MnO + C + 46·3$ Cals. also occurs at a high temp., as shown by A. Guntz, and R. Lorenz and F. Heusler. According to P. Berthier, manganese dioxide is formed when one of the higher manganese oxides is heated in a carbon crucible to the beginning of a white-heat. J. Mactear mixed a soln. of manganous sulphate with sufficient magnesium chloride to be eq. to the sulphate and any free sulphuric acid in the soln. When the liquid is evaporated out of contact with air, hydrogen chloride is copiously evolved and there is formed a mixture of manganous oxide and magnesium sulphate from which the latter can be removed by washing. J. von Liebig and F. Wöhler heated to redness a mixture of equal parts of manganous chloride, sodium carbonate, and ammonium chloride. The manganous carbonate first formed decomposes into the oxide, and the ammonium chloride prevents the formation of higher oxides. The fused mass is lixiviated, washed, and dried. D. C. Knab obtained the monoxide by heating one of the higher oxides with sulphur—some oxysulphide is also produced. J. J. Ebelmen prepared crystals of manganous oxide by heating manganese borate with lime ; crystals are also produced in J. von Liebig and F. Wöhler's process ; and H. St. C. Deville obtained crystals by reducing a higher oxide with hydrogen containing a trace of hydrogen chloride. A. Gorgeu heated to redness manganous chloride in water-vapour, with the exclusion of oxidizing gases, for a long time, and obtained crystals of manganous oxide. F. Doerinckel melted manganous oxide with silica and found that crystals of manganosite separated from the molten mass. V. Kohlschütter and J. L. Tüscher obtained an aerosol of manganese oxide by vaporizing the metal in an electric arc in a current of air.

According to P. Oberhoffer and K. d'Huart, when oxygen gas is passed over molten manganese, a molten green layer is formed on the surface of the metal. This layer contains a light-coloured constituent, which crystallizes first, and a dark-coloured, non-metallic constituent, which solidifies last. C. Benedicks

FIG. 44.—Part of the Equilibrium Curves of the System : Mn–O.

and H. Löfquist constructed a provisional equilibrium diagram, Fig. 44, based on the analogy between manganous oxide and ferrous oxide (*q.v.*). There is presumably a region of immiscibility, *ABC*, with manganous oxide and manganese ;
and a eutectic at D. The maximum at E refers to manganous oxide; and since the next higher oxide is manganosic oxide, Mn_3O_4, there is supposed to be a V-eutectic, at F.

The oxide was analyzed by J. A. Arfvedson, J. J. Berzelius, H. Davy, T. Bergman, H. Moissan, G. Forchhammer, and C. von Hauer, and the results are in agreement with the formula MnO. Manganosite was analyzed by C. W. Blomstrand, and C. Palache. G. Forchhammer, J. A. Arfvedson, E. Turner, J. J. Berzelius, J. von Liebig and F. Wöhler, and J. M. Weeren describe the monoxide as an amorphous or crystalline, green or greenish-yellow powder. W. Biltz discussed the colour of the derivatives of manganous oxide. H. St. C. Deville said that the emerald-green crystals are regular octahedra; while C. W. Blomstrand described the cubic crystals of manganosite as minute octahedra, which are emerald-green when fresh, and become black on exposure to air. According to A. Sjögren, the crystals resemble those of periclase. E. S. Larsen, and P. Klein found that manganosite is green in transmitted light. P. Klein studied the corrosion figures with hydrochloric and sulphuric acids. G. R. Levi found that the X-radiogram agrees with a cubical lattice of the sodium chloride type with $a=4.40$ A. and the calculated sp. gr. 5.46. A. J. Bradley obtained similar results with $a=4.45$ A. E. Broch gave $a=4.435$ A.; H. Ott, $a=4.47$ A. and a calculated density 5.22; and C. Fontana, $a=4.409$ A. and a density of 5.429. Observations were also made by V. M. Goldschmidt, G. Natta, and H. Ott. According to G. Aminoff, the radius of the hydrogen atom in the hydroxide is 1.05 A. The structure of the hydroxide is expressed by the substitution in $H_2O.O.H_2$ of the continuous hydrogen atoms of adjacent trigonal axes by manganese in the direction of these axes. E. J. Cuy gave 2.20 A. for the interatomic distance. According to W. Herapath, the specific gravity is 4.726 at 17°; while C. F. Rammelsberg gave 5.091; D. Müller, 5.4; L. Playfair and J. P. Joule gave 5.30; and V. H. Veley, 5.010 at 4°. G. R. Levi gave 5.432 for the sp. gr. of the fused oxide. C. W. Blomstrand gave 5.18 for the sp. gr. of manganosite, and 5 to 6 for the hardness. C. Palache gave 5.346 for the sp. gr. of manganosite. M. Meyer and B. Havas found the coeff. of cubical thermal expansion to be 0.0_622. H. V. Regnault gave 0.15703 for the specific heat between 13° and 98°. R. W. Millar found the molecular heat of manganous oxide to be:

	$-202.6°$	$-184.5°$	$-164.9°$	$-146.2°$	$-117.4°$	$-69.7°$	$-25.9°$	$-0.1°$	$37.2°$
C_p	4.426	6.348	9.829	7.470	8.124	9.173	9.729	9.992	10.3

The results are plotted in Fig. 45. There is a marked discontinuity between 110° K. and 118° K. I. Meydell studied the subject. C. M. Despretz found that

FIG. 45.—The Molecular Heats of the Manganese Oxides.

the oxide melts at a high temp. E. Tiede and E. Birnbräuer gave 1650° for the melting-point. J. H. Andrew and co-workers gave 1585°. C. Benedicks and H. Löfquist estimate the m.p. to be near 1700°. H. le Chatelier obtained for the heat of formation 90.8 Cals.; M. Berthelot, 90.9 Cals.; D. Müller, and W. A. Roth, 93.5 Cals.; and H. von Jüptner gave $2Mn+O_2=2MnO$ $+181.8$ Cals. G. Beck discussed the energy of formation. R. W. Millar calculated 14.92 for the entropy at 25°; and for $Mn+\frac{1}{2}O_2$ $=MnO$, the change of entropy is -17.0, and the change of free energy, $-85,830$ cals. G. Beck studied the energy of the oxide.

W. Biltz calculated for the temp. of dissociation, 4050° when $p=1$ atm. The temp. of dissociation and the e.m.f. series are in accord for the following metals and their oxides:

	Ag	Hg	Cu	Pb	Co	Fe	Mn
θ	488°	723°	2073°	2513°	3133°	3298°	4050°
Potential	$+0.771$	$+0.753$	-0.329	-0.151	-0.232	-0.344	-1.075 volts

H. Styri calculated for the **dissociation pressure** of manganous oxide, p, $2MnO=2Mn+O_2-181,600$ cals., log $p=-14.7$ at $1500°$; -13.5 at $1600°$; -12.4 at $1700°$. N. Parravano and G. Malquori gave for the dissociation pressure at $600°$ log $p_{O_2}=-37.573$. H. von Jüptner calculated for the dissociation $2MnO=2Mn+O_2$, the press. p atm., from log $p=-39562T^{-1}+1.75$ log $T=2.9$ (*vide infra*, MnO_2), so that:

	600°	1000°	1400°	1800°	2200°	2400°
p . .	$0.0_{56}5311$	$0.0_{31}3076$	$0.0_{19}1115$	$0.0_{13}3295$	0.0_94640	0.0_71703

W. E. Ford found the **index of refraction** for Na-light to be 2·18; and E. S. Larsen, 2·16. E. L. Nichols and D. T. Wilbur found manganese oxide showed no flame luminescence. T. W. Case observed no change in the electrical conductivity on exposure to light. O. F. Tower studied the potential of manganese dioxide electrodes in an alkaline soln. of manganous hydroxide. R. Whytlaw-Gray and co-workers, and E. Thomson found that the particles exhibiting Brownian movement form chains under the influence of an electrostatic field.

M. le Blanc and H. Sachse found the **electrical conductivity** to be 10^{-3} mho. E. Wedekind and C. Horst gave 56.16×10^{-6} mass unit for the **magnetic susceptibility** at $14.8°$; and P. Théodoridès, 67.46×10^{-6} mass unit. Comparative measurements were made by P. Hausknecht. E. H. Williams discussed the structure of the paramagnetic oxide. K. Honda and T. Sone's observations showed that the magnetic susceptibilities $\chi\times10^6$, at different temp., are:

	−189°	−76°	2°	275°	558°	738°	1013°	1149°	1296°
$\chi\times10^6$.	89·9	87·0	77·7	59·7	43·2	35·4	30·5	30·3	28·7

J. A. Arfvedson, and C. and A. Tissier found that manganous oxide is not decomposed by **hydrogen** at a bright red-heat; and F. Glaser observed that the decomposition by hydrogen begins at $1300°$; H. H. Meyer gave $1200°$. E. Newbery and J. N. Pring said that reduction occurs at $2000°$ with hydrogen at 150 atm. press. H. S. Taylor and A. T. Williamson found that the absorption of hydrogen is very small, and they studied its catalytic effect in the oxidation of hydrogen. J. V. Vaughan and W. A. Lazier studied manganous oxide as a catalyst in hydrogenation reactions. E. R. Schneider found that when strongly heated in **oxygen,** manganous oxide forms manganic oxide, Mn_2O_3. The monoxide obtained by reducing a higher oxide at a low temp. in hydrogen was found by C. R. A. Wright and A. E. Menke not to be spontaneously oxidized in **air** unless free alkali is present; but if a trace of alkali be present, the monoxide takes up oxygen from the air, and acquires a brown or black film. C. W. Scheele, and J. von Liebig observed that when the oxide is exposed to the air, it becomes brown in a few days; and if it be heated below redness, by red-hot charcoal, it glows rapidly to form manganosic oxide. N. N. Mittra and N. R. Dhar studied the oxidation of manganous hydroxide in air. H. Moissan found that the monoxide obtained by reducing higher oxides in hydrogen at $260°$ oxidizes with sparking at $140°$; and A. Gorgeu found that the oxide obtained by heating the oxalate at $200°$ to $420°$ is pyrophoric, forming manganosic oxide in air. The denser varieties of manganous oxide were found by J. A. Arfvedson to form manganosic oxide, without incandescence, at a dull red-heat. H. St. C. Deville found that the crystalline monoxide behaves similarly. H. V. Regnault observed that manganous oxide is not decomposed by boiling **water,** but when heated to redness in water-vapour, hydrogen and manganosic oxide are formed. A. von Kiss and F. E. Lederer studied the effect of manganese salts on the decomposition of **hydrogen dioxide.** R. Wasmuth studied the attack of the heated oxide by **chlorine.** L. E. Rivot and co-workers observed that in the presence of alkali-lye at $40°$ to $50°$ chlorine oxidizes it to alkali permanganate; at $0°$ manganic oxide is formed, which if the temp. be allowed to rise, passes into soln. as green alkali manganate. H. Rose found that **hydrochloric acid** dissolves manganese oxide to form manganous chloride, and if the monoxide be quite free from higher oxides, no chlorine is developed, and, according to L. Santi, the formation of manganous chloride.

C. Langlois observed that **periodic acid** is reduced to iodic acid, and·manganic iodate is formed.

J. A. Arfvedson found that when the monoxide is heated with **sulphur,** sulphur dioxide and manganese oxysulphide are formed ; while with **hydrogen sulphide,** water and manganese sulphide are produced. The reaction with sulphur vapour, and hydrogen sulphide was studied by K. Hilgenstock. R. Wagner obtained similar results. E. Priwoznik observed that **ammonium sulphide** at 100° converts it into flesh-coloured manganous sulphide. D. L. Hammick found that when manganous oxide is heated in **sulphur dioxide,** the reaction is accompanied by a dull red glow ; sulphur and sulphur trioxide are produced, as well as a green powder containing manganese sulphide and sulphate, as well as traces of the higher oxides. With a more prolonged heating to dull redness, there is a slow production of sulphur trioxide, but no free sulphur, and the brown solid becomes white manganous sulphate. The primary reaction is supposed to be $7MnO+10SO_2=MnS+6MnSO_4+SO_3+2S$; among other secondary reactions there is $MnS+5MnSO_4=2Mn_3O_4+6SO_2$. The reaction was studied by K. Hilgenstock. The oxide readily dissolves in **sulphuric acid** to form manganous sulphate.

O. Meyer found that manganese oxide is vigorously attacked by **titanium nitride** at a high temp. L. Santi observed that a hot conc. soln. of **ammonium chloride** converts manganous oxide into chloride, with the evolution of ammonia. P. Sabatier and J. B. Senderens found that **nitrous oxide** or **nitric oxide,** at 350°, converts manganese oxide into manganosic oxide without glowing ; while **nitrogen peroxide,** at 500°, forms manganic oxide. The oxide readily dissolves in **nitric acid** to form manganous nitrate, and in **phosphoric acid** to form the phosphate.

According to J. A. Arfvedson, and C. and A. Tissier, manganese monoxide is decomposed by **carbon** at a bright red-heat ; but not by **carbon monoxide.** H. C. Greenwood said that no reduction with carbon occurs at 500° to 600°, but at 1100° to 1200° it is reduced to manganese. N. Parravano and G. Malquori gave log p_{CO_2}—1·38 for the dissociation press. $2MnO+C=CO_2+2Mn$, at 1500°. H. H. Meyer said that the reaction with carbon starts at 900° to 950° ; and with carbon monoxide at 1200°. E. Nishibori studied the reaction with carbon monoxide. O. Meyer found that manganous oxide is attacked by **carbides**—silicon, chromium, and molybdenum—at a high temp. O. Houghton said that the reaction with silicon carbide begins at 1350°. The reaction was also studied by E. H. Schulz and A. Kanz. The reaction with **carbon disulphide** was studied by K. Hilgenstock ; and with ethyl and isopropyl alcohols, by A. T. Williamson and H. S. Taylor. E. Donath observed that **glycerol,** in alkaline liquids, dissolves manganous oxide, forming a red liquid in the presence of oxygen. J. Milbauer found manganous oxide is converted into potassium manganous sulphide when heated with **potassium thiocyanate.** P. Sabatier and A. Mailhe found that manganous oxide facilitates the catalytic reduction of **organic acids** to aldehydes and ketones. J. Aloy and C. Rabaut said that the presence of manganese oxide favours the saponification of benzoylated **cyanohydrins** by acetic acid. J. Fiedler found acid manganous oxalate is decomposed in light. G. Rauter found that when the monoxide is heated with **silicon tetrachloride,** manganous chloride, silica. and chlorine are formed. A. B. du Jassonnaix found that **boron** reduces the manganese oxides in an electric furnace. C. H. Burgess and A. Holt showed that the monoxide can dissolve in molten **boric oxide**—*vide infra,* manganous chloride and sulphate. L. Kahlenberg and W. J. Trautmann observed no reaction when a mixture of powdered **silicon** and manganous oxide is heated. For the reaction $MnO+Fe=FeO+Mn$, *vide* ferrous oxide. V. Macri studied the reducing action of salts of manganese oxide. He found that manganous sulphate completely precipitates the silver from a hot ammoniacal silver nitrate soln. The white precipitate formed by addition of the manganous salt to ammoniacal mercuric nitrate soln. turns grey and then brown on boiling, and, after treatment with sulphur dioxide soln. or an acidified soln. of a sulphite, leaves a heavy, brownish-

grey, pulverulent deposit, which is not dissolved by dil. nitric acid, but is readily attacked by the concentrated acid, with formation of nitrous fumes. When an ammoniacal soln. of copper and manganous sulphates is boiled, cuprous oxide is precipitated ; the supernatant colourless liquid gradually becomes blue in the air. The addition of ammonia to a soln. containing a cobalt and a manganous salt yields a precipitate of manganous hydroxide, which gradually becomes brown, not, however, by direct reduction of the cobalt oxide, since the latter first undergoes peroxidation in the air, and then gives up its oxygen to the manganese, especially on shaking. No tests were made with gold or platinum, but the hydroxides of other metals are not oxidized by manganous salts. R. Schenck and H. Wesselkock studied the action of manganese oxide on the oxidation of **nickel** and **cobalt** at 900° in an atm. of carbon dioxide. G. Natta and L. Passerini observed that **calcium oxide** forms an incomplete series of solid soln. with manganous oxide. When 75 to 100 per cent. of calcium oxide is present, the space-lattice has $a=4\cdot76$ to $4\cdot72$ A., when the space-lattice of manganous oxide has $a=4\cdot79$, and of calcium oxide, $a=4\cdot415$. When 35 to 50 per cent. of manganous oxide is present, the value of a falls, and two series of solid soln. are formed ; and when 75 to 90 per cent. of manganous oxide is present, the solid soln. has a lattice with $a=4\cdot42$ to $4\cdot48$. Incomplete miscibility occurs with calcium and manganous oxides. L. Passerini made analogous observations with **magnesium oxide,** which forms two series of solid soln. The mineral *manganbrucite*, $(Mg,Mn)O$, was found by L. H. Bauer and H. Berman to have the indices of refraction $\omega=1\cdot59$, and $\epsilon=1\cdot60$. F. de Carli found that **lead dioxide** at 250° to 300° oxidizes manganese oxide to a higher oxide. According to G. Natta and L. Passerini, and L. Passerini, **cadmium oxide** forms solid soln. with manganous oxide. Similarly, partial miscibility occurs with manganous oxide and **cobaltous oxide,** but incomplete miscibility with manganous oxide and **nickelous oxide.** J. H. Andrew and co-workers studied the solid soln. formed by mixtures with ferrous oxide. W. Biltz and co-workers obtained spinels, $MnO.R_2O_3$, with R_2O_3 represented by **alumina, ferric oxide,** and **chromic oxide.** W. Biltz discussed the mol. vol. of $MnO.Al_2O_3$. G. L. Clark and co-workers found the lattice constant, a, of the spinels, **manganese aluminate, chromite,** and **ferrite** to be respectively 8·271, 8·436, and 8·457 A. respectively. E. Diepschlag and E. Horn investigated the action of the oxide on ferric oxide, and the formation of manganous ferrite. H. Pélabon and M. Delwaulle observed that when manganous oxide is added to a conc. soln. of **mercuric chloride,** manganese oxides—Mn_3O_4, Mn_2O_3, and MnO_2—and mercurous chloride are formed. C. Montemartini and A. Vernazza studied the reaction with soln. of chromic sulphate.

L. J. Igelström found a **hydrated manganous oxide,** $MnO.H_2O$, or **manganous hydroxide,** $Mn(OH)_2$, in white crystals occurring at Pajsberg, Filipstadt, Sweden ; and A. Sjögren obtained it at Längbanshytta, and Nordmark, Sweden. The mineral was called **pyrochroite**—from πῦρ, fire, and χρόα, colour—in allusion to its change of colour on ignition. The mineral has also been reported by L. J. Igelström, from Grythyttan, Oerebro, Sweden ; by G. A. Kenngott, from St. Gallen, Switzerland ; and by J. D. Dana, from Franklin Furnace, New Jersey. The so-called *wiserite* of W. Haidinger was reported by D. F. Wiser to be a manganous carbonate, but G. A. Kenngott showed that it is the hydrated oxide. Analyses of pyrochroite were reported by L. J. Igelström, H. Sjögren, A. E. Nordenskjöld, and L. Stahre. P. Groth represented it by the formula $Mn(OH)_2$, and H. Laspeyres regarded H_2MnO_2 as *manganous acid* or as *hypomanganous acid*. G. Aminoff described a rhombic modification of the $Mn(OH)_2$ which he found more or less altered in the limestone at Langban, Sweden ; and he called it **bäckströmite**—after H. Bäckström. X-radiograms of the altered mineral show that it has more or less changed to pyrochroite. The rhombic crystals have the axial ratios $a:b:c=0\cdot7393:1:0\cdot6918$. Some crystals have a good cleavage parallel to (010). Hydrated manganous oxide is formed as a white precipitate when alkali hydroxide is added to a soln. of a manganous salt. It is not soluble in an excess of alkali-lye,

but is dissolved by ammonium chloride soln., and it gradually becomes brown on exposure to air. H. E. Patten observed that if precipitated from a soln. of manganous chloride and potassium sulphate, the precipitate is contaminated with adsorbed sulphate. E. Donath showed that the presence of glycerol, J. Lefort and P. Thibault the presence of gum arabic, and O. Tamm the presence of sodium tartrate or citrate, or cane-sugar, hinder the precipitation.

C. A. L. de Bruyn observed that a soln. of **colloidal manganous hydroxide** is formed by treating a soln. of a manganous salt with alkali in the presence of gelatin, or albumen (A. Trillat), nucleic acid (L. Sarason), or glycogen (L. Hugounenq and J. Loiseleur). W. Spring and G. de Boeck, and W. Knaust obtained it by treating a soln. of potassium permanganate with sodium hyposulphite. O. Fisseler prepared colloidal manganous hydroxide by adding the calculated quantity of manganese sulphate to a soln. of 3 grms. of sodium protalbinate or lysalbinate in water. By adding soda-lye, a milk-white turbidity is produced by the colloidal manganous hydroxide. This can be dialyzed, and evaporated over a water-bath at 70°, and finally over sulphuric acid in vacuo. The scaly product forms a brown sol with water. Kalle and Co. also prepared the colloid in an analogous way—*vide infra* for K. C. Sen and N. R. Dhar's observations. H. E. Patten observed that when alkali hydroxide is added to a soln. of a manganous salt, white, gelatinous manganous oxide is precipitated. The hydrated oxide adsorbs chlorides slightly and sulphates strongly, so that chlorides are not adsorbed in the presence of sulphates. The fine state of subdivision of the colloid favours its oxidation to the hydrated dioxide, and, according to G. Bertrand, and A. Villiers, the hydrated dioxide again forms colloidal manganous oxide in the presence of reducing agents like hydroquinone or gallic acid. The manganous hydroxide thus acts as an oxydase or oxygen-carrier in catalyzed reactions—*e.g.* the rapid drying of manganese oxide paints, varnishes, and siccatives—and A. Livache considers that the drying oil—*e.g.* linseed oil—plays the double rôle of protective colloid and oxygen-consuming reducing agent.

The hydrated oxide is partially precipitated by ammonia from soln. of manganous salts, and, according to C. Vincent, by dimethylaniline. H. Rose observed that tartaric acid hinders the precipitation by ammonia. According to W. Herz, a mixture of equal vols. of normal soln. of manganous sulphate and ammonium chloride in an atm. of hydrogen gives a cloudiness on the addition of about one and a half times the quantity of $0.1N$-soln. of ammonia; the further addition of ammonia does not appreciably increase the precipitate, which is deposited after the mixture has remained for some hours. The reaction which takes place when manganous hydroxide is treated with soln. of ammonium chloride, nitrate, and sulphate in an atm. of hydrogen is expressed by the equation $Mn(OH)_2 + 2NH_4Cl \rightleftharpoons MnCl_2 + 2NH_4OH$. The reaction does not follow the laws of mass reaction, and the results do not agree with those obtained by J. M. Lovén for magnesium salts. The abnormal results are probably due to the combination of the manganese and ammonia to form complex cations. T. Curtius and F. Schrader found that hydrazine hydrate also precipitates the hydrated monoxide. H. W. Morse showed that there is evidence of a periodicity in the precipitation of the hydroxide. M. Pariselle and M. Laude discussed the joint precipitation of manganous hydroxide and alumina. W. Knaust studied the coagulation of the sol peptized by phosphoric acid.

R. Lorenz obtained the hydroxide electrolytically using a platinum cathode, a plate of manganese as anode, and aq. soln. of alkali chloride, sulphate, or nitrate. A. C. Becquerel obtained tabular crystals of the hydrated monoxide by electrocapillary action between soln. of potassium hydroxide and manganous nitrate. E. Weinschenk, and A. Commaille prepared crystals of the hydrate by allowing manganous oxide to stand in contact with ammoniacal soln. According to A. de Schulten, artificial pyrochroite is produced by the following process :

300 grms. of potassium hydroxide are dissolved in 500 c.c. of water, boiled for some

time in a flask through which a current of hydrogen or coal gas is passing, and a recently boiled soln. of 15 to 17 grms. of crystallized manganous chloride in 15 c.c. of water is introduced by means of a funnel with a stopcock. The flask is then heated to about 160°, when the whole of the manganous hydroxide dissolves. As the liquid cools, it deposits crystallized manganous hydroxide, and becomes almost solid. The crystals are washed with recently-boiled water, alcohol, and ether, and dried at a gentle heat in a current of hydrogen. If sodium hydroxide is used, the precipitate does not dissolve even in conc. soln. at 200°, but it becomes crystalline.

Pyrochroite is white, but becomes bronze-coloured and then black on exposure to air; thin pieces appear flesh-coloured in transmitted light. The mineral usually occurs foliated like brucite, and, according to G. Flink, it furnishes trigonal, tabular, or columnar crystals with the axial ratio $a : c = 1 : 1.3999$; G. Aminoff gave $1 : 4004$, and added that it is isomorphous with brucite. The basal cleavage is complete. The crystals were studied by J. Beckenkamp. W. Knaust observed that the precipitated hydrogel is at first amorphous, but becomes crystalline with increasing age. The hydrosol coagulates in 30 minutes at 100°, in 90 minutes at 80°, and in 255 minutes at 60°. G. Aminoff found that the X-radiograms agreed with a space-lattice having the dimensions $a = 3.34$ A., $c = 4.68$ A., and $a : c = 1 : 1.40$, and one mol. per unit cell. G. Natta discussed the isomorphism of the rhombohedral bivalent hydroxides from the point of view of the space-lattice, and the radius of the metal ions. G. Natta and L. Passerini studied the isomorphism of the cadmium and manganous hydroxides. H. Sjögren studied the percussion figures and observed that the birefringence is strong and negative; and the indices of refraction for red-light are $\omega = 1.723$, and $\epsilon = 1.681$. The pleochroism is strong. A. de Schulten described the artificial crystals as flattened, transparent, hexagonal prisms as with polychroite. The crystals have a reddish tinge. The precipitated hydroxide is white and flocculent. G. Natta and L. Passerini observed the formation of solid soln. of manganous and cadmium hydroxides by precipitation. A. de Schulten gave 3.258 for the sp. gr. of the artificial crystals at 13°; and H. Sjögren, 3.2435 for the mineral crystals. P. Hausknecht found the magnetic susceptibility to be nearly $2\frac{1}{2}$ times that of manganous oxide, and P. Koechlin gave 3.3. The hardness is 2 to 3. H. le Chatelier gave for the heat of formation $(Mn,O) = 90.8$ Cals.; and $(Mn,O,H_2O) = 94.7$ Cals. J. Thomsen, 94.8 Cals., and M. Berthelot, 95.1 Cals. J. Thomsen gave for the heat of neutralization with sulphuric acid 26.48 Cals.; hydrochloric acid, 22.95 Cals.; nitric acid, 22.95 Cals.; and dithionic acid, 22.78 Cals. J. Thomsen also gave for the heat of oxidation of the hydrated monoxide to the hydrated dioxide, 21.511 Cals. F. Allison and E. J. Murphy studied the magneto-optic properties.

J. Meyer and W. Gulbins found that when alkaline soln. of colloidal manganous hydroxide in gelatin are exposed to air, oxidation to manganic oxide occurs in a few days; if a few drops of perhydrol be present, the oxidation does not go entirely to manganic oxide; with ammoniacal soln. manganic oxide is formed; and with potassium manganicyanide, manganic hydroxide is formed. Alkaline soln. of colloidal manganous hydroxide were completely oxidized to manganic oxide in five days. O. Sackur and E. Fritzmann gave for the **solubility product** $[Mn\cdots][OH]^2 = 4 \times 10^{-14}$, and H. T. S. Britton, 1.3×10^{-14}. W. R. G. Atkins found that the precipitation of the hydroxide from a soln. of manganous chloride occurred when the H·-ion conc. is between $p_H = 8.6$ and 9.2; and H. T. S. Britton, when $p_H = 8.85$. The results for the **electrometric titration** of manganous chloride soln obtained by H. T. S. Britton with 0.9N-NaOH, and 100 c.c. of 0.24M-MnCl$_2$, at 18°, are summarized in Fig. 46. According to B. Schrager, manganous hydroxide shows acidic properties.

G. Aminoff observed that analyses of the mineral bäckströmite—*vide supra*—

Fig. 46.—Electrometric Titration of a Solution of Manganous Chloride.

show that the composition is nearer that of manganite. There is an excess of oxygen beyond that required for manganous oxide. The crystals represent double pseudomorphs, bäckströmite→pyrochroite→manganite. The compounds $Mg(OH)_2$, $Ca(OH)_2$, and $Cd(OH)_2$ form a trigonal series, and $Ca(OH)_2$ and $Zn(OH)_2$ a rhombic series.

A. de Schulten said that the crystalline hydroxide furnishes grey manganous oxide when it is heated in hydrogen. The white, precipitated hydroxide turns brown in air, forming, according to R. Phillips, brown, hydrated dioxide ; and, according to W. Weldon, brown manganic hydroxide, or, in the presence of calcium hydroxide and chloride, calcium manganite. A. Gorgeu added that in the presence of water and an excess of manganous salt, it is rapidly oxidized to hydrated manganosic oxide, and then to hydrated manganic oxide. C. Engler and J. Weissberg found that some manganese dioxide and hydrogen dioxide are formed during the oxidation of manganous hydroxide. According to J. Meyer and R. Nerlich, manganous hydroxide in suspension or in colloidal soln. is oxidized by atm. air directly to manganese dioxide, whilst complex manganous salts in ammoniacal or alkaline soln. are oxidized to manganic hydroxide. Manganous ions are not oxidized at all by atm. oxygen. Acceptors such as sodium sulphite or arsenite had no influence on the velocity or course of the reaction. Manganous hydroxide precipitated by sodium, potassium, calcium, or barium hydroxide gave in each case manganese dioxide, but a soln. of manganous hydroxide in excess of ammonia in presence of ammonium chloride gave a precipitate of manganic hydroxide of a characteristic yellowish-brown colour—*vide infra*, manganous chloride. The subject was studied by D. Köszegi.

A. de Schulten observed that when the crystalline hydroxide is heated to redness in air, the manganosic oxide which is produced retains the form of the original hydroxide ; and while crystalline manganous hydroxide alters very slowly in air, the oxidation proceeds rapidly in the presence of traces of alkali. The oxidation products were discussed by D. Köszegi. W. Herz gave 0.6×10^{-4} mol $Mn(OH)_2$ per litre for the solubility of the hydrated oxide ; O. Sackur and E. Fritzmann gave 2.15×10^{-5} at 18° ; and O. Tamm gave 2×10^{-4}. A. Quartaroli observed that the hydroxide has no influence on the decomposition of hydrogen dioxide by silver oxide. F. Muck observed that the hydrated monoxide is rapidly oxidized to the hydrated dioxide by chlorine, and bromine, while the oxidation is slow with iodine. Crystalline manganous hydroxide was found by A. de Schulten to dissolve readily in hydrochloric acid, and in a soln. of ammonium chloride. R. H. Brett found that the soln. of manganous hydroxide, carbonate, or phosphate gives no precipitate with hydrogen sulphide. C. Langlois found that periodic acid is reduced to iodic acid. J. B. Senderens observed that when the hydroxide is boiled with sulphur and water, manganous thiosulphate is formed ; and F. Muck noted that the fresh precipitate is easily transformed into manganous sulphide by ammonium sulphide, and with difficulty by sodium sulphide. J. Meyer and W. Schramm studied the action of sulphur dioxide (*q.v.*). F. Kuhlmann observed no reducing action on nitric oxide. O. Tamm found that the solubility of manganous hydroxide in a $0.5N$-soln. of sodium tartrate is 0.0068 mol per litre ; $0.5N$-soln. of sodium malate, 0.0042 mol per litre ; and $0.5N$-soln. of sodium citrate, 0.0126 mol per litre. E. Donath said that the hydroxide is soluble in glycerol soln. ; and K. C. Sen and N. R. Dhar observed that manganous hydroxide is not precipitated by alkali hydroxide from soln. containing sucrose, dextrose, lævulose, galactose, lactose, mannose, dextrin, starch, or glycerol, probably owing to the peptization of the hydroxide to form a colloidal soln. C. and A. Tissier found that boric acid soln. dissolve it, forming a liquid stable in air. J. Post found that the hydrated monoxide is soluble in soln. of manganous chloride, and of calcium chloride. According to K. Milberg, freshly-precipitated manganous hydroxide reacts quantitatively with copper sulphate, forming manganous sulphate and copper hydroxide. H. Pélabon and M. Delwaulle investigated the action of mercuric chloride on man-

ganous oxide, and obtained products analogous to those obtained by the action of mercuric oxide on manganous chloride (q.v.). R. Schenck and H. Wesselkock examined the accelerating influence of manganese oxide on the equilibrium between cobalt oxide and hydrogen.

§ 9. Manganosic Oxide, or Manganese Tritatetroxide

The *schwarz Braunsteinerz* of A. G. Werner,[1] the *schwarz Manganerz* of D. L. G. Karsten, and the *blättricher schwarz Braunstein* of J. F. L. Hausmann were called by W. Haidinger **hausmannite**—after J. F. L. Hausmann. It occurs near Ilmenau, Thuringia; Ilefeld, Harz; Filipstad, Wermland; Längban, Jakobsberg, Nordmark, and Grythyttan, Sweden; Framont, Alsace, etc. Analyses reported by E. Turner, W. V. Smitheringale, C. F. Rammelsberg, H. D. Miser and J. G. Fairchild, L. J. Igelström, and A. Gorgeu are in agreement with the formula for **manganosic oxide**, $MnO.Mn_2O_3$—that is, **manganese tritatetroxide**, Mn_3O_4. Similarly with analyses of the artificial product reported by J. A. Arfvedson, J. J. Berzelius, T. Bergman, G. Forchhammer, E. R. Schneider, and M. Schaffner. P. Berthier regarded this oxide as a compound, $2MnO.MnO_2$, on account of its behaviour towards conc. nitric acid; and R. Hermann adopted a similar hypothesis because Mn_3O_4 and Fe_3O_4 are not isomorphous; and the hypothesis was favoured by C. F. Rammelsberg, and B. Franke. H. Laspeyres regarded it as a salt of the acid $H_{10}MnO_8$, namely, Mn_5MnO_8. A. Gorgeu at first adopted P. Berthier's hypothesis, but later, in view of O. T. Christensen's observation that dil. acetic acid splits the oxide into manganous and manganic acetates, and H. Rose's observations on the action of a soln. of ammonium chloride, he regarded it as *manganous hypomanganite*, $MnO.Mn_2O_3$, or $Mn(MnO_2)_2$. H. D. Miser and J. G. Fairchild represented it by the formula Mn_2MnO_5. P. Groth, and several other writers also regard it as a salt of *orthomanganous acid*, H_4MnO_4, namely, $Mn_2(MnO_4)$, or *manganous orthomanganite*. J. Meyer and R. Kanters—*vide supra*—showed that Mn_3O_4 is better regarded as $MnO.Mn_2O_3$, than as $2MnO.MnO_2$.

Manganese tritatetroxide is formed when manganese oxidizes in air at ordinary temp., and more rapidly when heated in oxygen; the powdered metal oxidizes with a glow. Manganous oxide glows when heated in air, forming this oxide, and it is also formed, according to H. V. Regnault, when manganous oxide is heated in steam. The higher oxides of manganese form the tritatetroxide when strongly heated. T. Sidot obtained crystals of the oxide in this way. W. Biltz represented the reaction by the equation: $6Mn_2O_3 = 4Mn_3O_4 + O_2 - 50.4$ Cals., and found for the press. of the oxygen, p atm., at different temp.:

	887°	940°	1007°	1090°	1127°
p . . .	0.045	0.21	0.42	1.00	2.69

This subject was examined by P. Askenasy and S. Klonowsky, C. R. Fresenius, L. Wöhler and O. Balz, C. Friedheim, and F. A. Gooch and M. Austin—*vide infra*, manganese hemitrioxide. C. R. A. Wright and A. P. Luff, I. L. Bell, and C. R. Fresenius also observed that the tritatetroxide is formed when manganous carbonate or hydroxide is vigorously heated in air; and J. L. Lassaigne obtained a similar result with manganous oxalate. J. Volhard obtained it by heating a mixture of mercuric oxide and manganous chloride. Crystals of the tritatetroxide are formed, according to H. St. C. Deville, when the amorphous oxide is heated to redness in a slow current of hydrogen chloride. C. von Hauer obtained the crystals by heating ammonium manganous chloride or a mixture of ammonium chloride and manganous oxide in air; H. Debray, by strongly heating a mixture of manganous and potassium sulphate; A. Daubrée, and H. Debray, by heating

manganous chloride in steam; A. E. Nordenskjöld, by heating the amorphous oxide with borax; F. Kuhlmann, by roasting a mixture of calcium chloride and manganous oxide; P. Ebell, by heating the oxide with glass—on cooling the manganese tritatetroxide separates out in crystals; and L. Bourgeois, by heating a mixture of manganese dioxide and silica. F. Kuhlmann also observed crystals of this oxide as a furnace product.

Hausmannite occurs granular and massive, as well as crystalline, and its colour is brownish-black with a chestnut-brown, or, according to J. L. C. Schröder van der Kolk, a reddish-brown streak. Hence it is also called *red oxide of manganese*. O. Mügge said that in very thin layers the **colour** is deep brownish-red. W. Biltz discussed the colour of the derivatives of this oxide. The tetragonal **crystals** were found by W. Haidinger to have the axial ratio $a : c = 1 : 1 \cdot 1743$; G. Flink gave $1 : 1 \cdot 1573$, and V. Goldschmidt, $1 : 1 \cdot 1554$. The habit is usually octahedral; the (113)-faces are usually bright and smooth, the (111)-face striated, and the (111) : (113)-edge, dull. **Twinning** occurs about the (101)-plane, and the twinning may be repeated to fivelings. The (001)-**cleavage** is nearly perfect, but the (101)- and (111)-cleavages are indistinct. The crystals were also examined by H. Dauber, J. Orcel and S. Pavlovitch, and R. Koechlin. M. L. Huggins examined the structure by the **X-radiogram** method. G. Aminoff found that the X-radiograms of the crystals agree with the assumption that the space-lattice is body-centred and tetragonal, with $a = 5 \cdot 75$, and $c = 9 \cdot 42$ A., or face-centred, with $a = 8 \cdot 14$, and $c = 9 \cdot 42$ A. There are eight mols. of $Mn(Mn_2O_4)$ per unit cell. The general structure resembles that of magnetite, except that the axial ratio is $a : c = 1 : 1 \cdot 16$ instead of $1 : 1$. W. V. Smitheringale discussed the X-radiogram, and the etching of the mineral with different etching liquids; G. A. Thiel also discussed the action of various reagents—hydrochloric and sulphuric acids, hydrogen dioxide, and soln. of ferrous and stannous chlorides. S. Holgersson observed no evidence of a cubic form.

C. F. Rammelsberg gave 4·856 for the **specific gravity** of hausmannite; W. Haidinger, 4·722; and A. Gorgeu, 4·91. For the artificial oxide A. Gorgeu gave 4·80; L. Playfair and J. P. Joule, 4·325 to 4·746; and C. F. Rammelsberg, 4·718; and for the dispersed oxide H. P. Walmsley gave 4·709. The **hardness** of hausmannite is 5·0 to 5·5. The coeff. of cubical **thermal expansion** was found by L. Playfair and J. P. Joule to be 0·00522 between 0° and 100°. E. Jannettaz made observations on the relative **heat conductivity** of the crystals in different directions. P. E. W. Oeberg gave 0·1520 for the **specific heat.** R. W. Millar found the **molecular heat** of manganosic oxide, Mn_3O_4, to be :

	−200·8°	−169·4°	−121·1°	−72·6°	−20·5°	−1·5°	32·2°
C_p	9·725	15·02	22·14	27·37	31·28	32·45	33·46

The results are plotted in Fig. 36. J. Maydell studied the mol. ht. G. Spezia observed that hausmannite melts to a black enamel in the gas-flame fed with warm air; and O. Mügge observed that no oxygen is given off or absorbed between 940° and 1300°. H. von Wartenberg and W. Gurr gave 1705° for the **melting-point.** M. Berthelot, and H. le Chatelier both found the **heat of formation** to be $(3Mn, 2O_2)$ $= 328$ Cals.; D. Müller, and W. A. Roth, 345 Cals.; and O. Ruff and E. Gersten, 329 Cals. A. Simon and F. Feher gave $(6MnO, O_2) = 72$ Cals.; R. W. Millar gave 35·73 for the **entropy** of Mn_3O_4; and for the reaction $3Mn + 2O_2 = Mn_3O_4$ he gave the change of entropy −84·6 at 25°, and for the change of **free energy,** −302,800 cals. E. S. Larsen gave for the **indices of refraction** $\omega = 2 \cdot 46$, and $\epsilon = 2 \cdot 15$. The crystals are not pleochroic and the optical character is negative. R. D. Harvey examined the **electrical conductivity.** T. W. Case observed no change in the electrical conductivity on exposure to light. W. Flight observed no **thermoelectric current** with hausmannite. E. Wedekind and C. Horst found the **magnetic susceptibility** to be $65 \cdot 5 \times 10^{-6}$ mass unit at 15·5°. E. Feytis found $74 \cdot 3 \times 10^{-6}$. K. Honda and T. Sone found that the magnetic susceptibility, $\chi \times 10^6$, changes

abruptly with temp. at 1080°, corresponding with the passage of manganosic oxide to manganous oxide :

$\chi \times 10^6$	$-175°$	$-99°$	$20°$	$304°$	$559°$	$794°$	$1080°$	$1198°$
	126·0	76·0	55·8	40·7	33·3	28·2	25·6	24·7

J. Meyer and R. Kanters observed that the chemical behaviour of manganosic oxide favours the view that the manganese in it is tervalent, and that the oxide is to be regarded as $MnO.Mn_2O_3$, rather than as $2MnO.MnO_2$. When manganosic oxide is heated to redness in **hydrogen,** it is reduced to manganous oxide (q.v.). According to W. Müller, when manganese dioxide is heated in hydrogen at 202°, it forms Mn_3O_4; and, according to H. Moissan, the artificial dioxide in dry hydrogen at 230° passes into Mn_2O_3, and at a higher temp. into MnO. W. Müller said that the action with Mn_3O_4 begins near 330°, and progresses slowly at 360°, while C. R. A. Wright and A. P. Luff found that the reduction of the amorphous oxide begins at 255°; and F. Glaser found that manganese dioxide passes into manganosic oxide in hydrogen, and at 296° it passes into manganous oxide. E. R. Schneider found that when heated in **oxygen,** manganosic oxide passes into manganic oxide, and, added A. Gorgeu, this occurs the more easily the finer the state of subdivision; the oxidation begins at 170° and involves the intermediate formation of $2MnO.3MnO_2$. A. Gorgeu, and M. Martinon also studied the action of **hydrogen dioxide**—*vide infra,* manganese dioxide. F. J. Otto observed that when heated with **hydrochloric acid,** manganous chloride and chlorine are formed. H. Rose observed that a hot soln. of **ammonium chloride** dissolves manganous oxide, leaving a residue of manganic oxide, while when manganosic oxide is heated with ammonium chloride, manganous chloride is formed. H. Rose also observed that when heated with **sulphur** in hydrogen, manganous sulphide is formed. C. W. Davis studied the action of sulphurous acid. E. Turner found that when treated with boiling **sulphuric acid** (1 : 11), a soln. of manganous sulphate and nearly the theoretical proportion of manganese dioxide—$Mn_3O_4 = 2MnO + MnO_2$— are formed—*vide infra,* manganosic sulphate. G. Forchhammer found that with hot, conc. sulphuric acid, oxygen and manganous sulphate are formed; and when heated with potassium hydrosulphate, 100 parts of manganosic oxide give 7·566 parts of oxygen—theory for $Mn_3O_4 = 3MnO + O$ corresponds with 7 parts of oxygen. According to P. Berthier, and G. Forchhammer, boiling conc. or dil. **nitric acid** extracts manganous oxide, and leaves manganese dioxide, in accord with $Mn_3O_4 = 2MnO + MnO_2$. The influence of mercury on the action was studied by J. Meyer and R. Kanters: $Mn_3O_4 + 2Hg + 8HNO_3 = 2HgNO_3 + 3Mn(NO_3)_2 + 4H_2O$. H. Rose found that when treated with syrupy **phosphoric acid,** manganic phosphate is formed. P. Berthier found that manganosic oxide is reduced to the metal when it is heated to a high temp. with **carbon.** F. Fischer and F. Bangert observed that **methane** reacts with the oxide at 800° to 1000° to form a carbide. A. Kutzelnigg observed that a soln. of **potassium ferrocyanide** is oxidized by manganosic oxide. The trita-tetroxide is reduced when heated with **carbon monoxide,** forming manganous oxide (q.v.)— I. L. Bell said that the reaction occurs at the m.p. of zinc; C. R. A. Wright and A. P. Luff found that the action begins at 240°. O. T. Chris-

FIG. 47.—The Melting-Point Curve of the System: ZrO_2–Mn_3O_4.

tensen found that **acetic acid** attacks the calcined oxide the less the stronger the acid, and at 100° the acetic acid forms a mixture of manganous and manganic acetates. H. C. Bolton found that **citric acid** attacks hausmannite, and if

potassium iodide is present, a brownish-red soln. is formed. W. Thomson and F. Lewis studied the action on **indiarubber.** H. von Wartenberg and W. Gurr found that **zirconia** reacts with manganosic oxide, Mn_3O_4, as summarized by the m.p. curve, Fig. 47. According to R. Wagner, when manganosic oxide is heated with **alkali carbonate and nitrate** out of contact with air, nitric oxide is given off : $6Mn_3O_4 + 2KNO_3 = 9Mn_2O_3 + K_2O + 2NO$; the product does not form a green colour when dissolved in dil. soda-lye.

Manganosic oxide dissolves in hot, conc. phosphoric acid, hot acetic acid, and cold, conc. sulphuric, hydrochloric, oxalic, or tartaric acids without neutralizing the acid. The soln. in phosphoric and sulphuric acids are columbine-red, and those in the other acids are dark brown. The liquids probably contain a mixture of manganic and manganous salts. Heating, diluting with water, or treating with reducing agents transforms the soln. into that of a manganous salt. If the soln. in acid be treated with potash-lye, what has been regarded as **hydrated manganosic oxide** is precipitated. According to F. J. Otto, when an ammoniacal soln. of manganous chloride containing ammonium chloride is treated with an excess of freshly-precipitated hydrated manganese dioxide, and the soln. gradually heated, a yellowish-brown hydrated manganosic oxide is precipitated. O. T. Christensen prepared it by a similar process. According to F. J. Otto, a similar product is obtained when ammonia is added to an ammoniacal soln. of manganous chloride, containing ammonium chloride, which has been exposed to the air for a long time. It is also formed by the action of an ammoniacal soln. of ammonium sulphite on hydrated manganese dioxide—the reaction is slow in the cold, but rapid if heated. A. Gorgeu obtained it by shaking a soln. of a manganous salt with alkali in air ; C. F. Rammelsberg, by allowing a soln. of a manganous salt to stand exposed to air for a long time ; and H. Schjerning, by the action of a mixture of sodium sulphide and thiosulphate on potassium permanganate. R. Lorenz made the hydrated oxide by electrolyzing an aq. agitated soln. of sodium chloride, sulphate, or nitrate with a platinum cathode and a manganese anode.

The yellowish-brown product has a slight tinge of red. F. J. Otto added that it is not altered by a boiling soln. of ammonium chloride, but it is decomposed by dil. acids into a manganous salt and brownish-black hydrated dioxide. According to O. T. Christensen, the colour of the precipitated hydrated oxide may be yellow, brown, reddish-brown, or chocolate-brown, according to conditions of formation. A. Gorgeu obtained it as a chocolate-brown crystalline mass, and found that dil. nitric oxide yields two-thirds of the manganese as manganous nitrate and one-third as hydrated dioxide. The air-dried hydrate contains 3·5 to 27 per cent. of water, and that dried in vacuo has 2·5 to 7 per cent. of water. J. Post found that if hydrated manganosic oxide be heated 15·5 hrs. to 250° to 300°, it takes up oxygen to form manganic oxide.

L. L. Fermor described a mineral from Beldongu, Central Provinces, India, and called it **vredenburgite.** Its composition approximates $3Mn_3O_4.2Fe_2O_3$. It forms brownish-black or chocolate-brown octahedral or tetragonal pyramids of sp. gr. 4·74 to 4·84 and hardness 6·5. The mineral **rancieite,** or *rancierite,* a hydrated manganese oxide from Rancié, Ariège, France, was described by A. Leymerie, and A. Lacroix, and was probably the *manganèse argentin* of R. J. Haüy. According to J. O. Haas, that from Lacampe, Aude, France, has the formula $MnO_2.2MnO.2H_2O$, with some bivalent manganese replaced by lime, ferrous iron, or alkalies. The sp. gr. is 3·25 to 3·30.

§ 10. Manganic Oxide, or Manganese Hemitrioxide

The mineral braunite—named after M. Braun—was described by W. Hai dinger [1]; it was called *Hartbraunstein* by J. F. L. Hausmann; *marceline*, by F. S. Beudant; *Heterokline*, by A. Breithaupt; and *leptonematite* and *pesillite*, by M. Adam. It occurs near Ilmenau, and Elgersburg, Thuringia: Ilefeld, Harz; St. Marcel, Piedmont; at Elba; at Botnedal, Norway; at Jakobsberg, Längban, Grythyttan, and Glakärn, Sweden, Vizianagram, Bimlipatam, etc., in India; and in the Wellington district, etc., in New South Wales. Analyses were reported by C. F. Rammelsberg, F. Buckeisen, H. Rose, J. J. Berzelius, P. Berthier, A. J. Scott, F. R. Mallet, G. Flink, C. von Evreinoff, W. Elderhorst, A. A. Damour, T. Scheerer, E. Turner, E. Schweizer, G. Meneghini, B. Jezek, A. Gorgeu, A. Liversidge, and L. L. Fermor. Braunite is usually associated with silica, and C. F. Rammelsberg represented it by the formula $3Mn_2O_3.MnSiO_3$, and later gave $MnO.(Mn,Si)O_2$. A. Gorgeu regarded it as a salt with the general formula $RO(Mn,Si)O_2$; whilst G. Flink, and L. L. Fermor represented it by the formula $mRMnO_3.nRSiO_3$ where $m:n$ is usually between $4:1$ and $3:1$; R is mainly Mn. E. Turner probably overlooked the presence of silica, and represented braunite by the formula Mn_2O_3, but R. F. Penrose, and G. Meneghini reported samples respectively from Arkansas and Elba to be virtually free from silica. F. von Kobell regarded the silica as a non-essential constituent of braunite. R. Hermann regarded the mineral as a compound $MnO.MnO_2$, and this is in agreement with E. Turner's observations that dil. acids decompose the mineral into a mixture of MnO and MnO_2. G. Rose pointed out that braunite appears to have a constitution different from that of artificial manganese hemitrioxide, which can replace alumina and ferric oxide in epidote and manganic alum, while braunite seems to behave like a salt. O. T. Christensen regarded braunite as a sesquioxide, but H. Laspeyres supposed it to be a manganese salt of orthomanganous acid, H_6MnO_6, namely, Mn_3MnO_6, and P. Groth considered braunite to be a salt of metamanganous acid, H_2MnO_3, namely, $MnMnO_3$, mixed with more or less metasilicate, $MnSiO_3$. The artificial oxide was analyzed by G. Forchhammer, J. A. Arfvedson, H. Davy, J. F. John, H. Moissan, and E. R. Schneider; and J. Meyer and R. Kanters showed that it contains tervalent manganese.

According to J. R. Blum, braunite occurs in nature in pseudomorphs after manganite. S. Meunier prepared black, octahedral crystals with a brown streak by melting manganese dioxide with cryolite—some corundum, and manganese aluminate are formed at the same time. According to J. J. Berzelius, and R. Hermann, manganese hemitrioxide is formed when manganese dioxide or manganous nitrate is heated to dull redness in air. E. R. Schneider obtained the hemitrioxide by heating the dioxide, the tritatetroxide, or the monoxide in oxygen. W. Dittmar found that at the temp. of a bunsen flame manganese tritatetroxide is the main product. C. F. Rammelsberg obtained the hemitrioxide by heating manganite at dull redness, and L. Carius by heating artificial manganic hydroxide. W. Biltz represented the reaction with manganese dioxide by the equation: $4MnO_2=2Mn_2O_3+O_2-30.9$ Cals., and he found for the press. of oxygen, p atm., at different temp. :

	477°	530°	565°	587°
p	0.065	0.21	1.00	1.20

R. J. Meyer and K. Rötgers found that the reactions $MnO_2 \rightleftharpoons Mn_2O_3 \rightleftharpoons Mn_3O_4$ are reversible, and that manganese dioxide passes into the hemitrioxide at 530° in air and at 565° in oxygen; while manganese hemitrioxide passes into the tritatetroxide at 940° in air and 1090° in oxygen—*vide supra*, manganese tritatetroxide. These observations are not fully in agreement with those of P. Askenasy and S. Klonowsky, discussed in connection with manganese dioxide. H. Moissan observed that the artificial dioxide in dry hydrogen passes into the hemitrioxide at 230°. R. Bunsen and G. Krieger observed that when precipitated by means of

sodium carbonate from a mixed soln. of a manganous salt and a copper, calcium, strontium, barium, magnesium, zinc, cadmium, lead, or bismuth salt, and the washed precipitate is calcined in air, the manganous hydrate is converted into manganese hemitrioxide ; and A. Classen obtained a similar result when a mixed precipitate of zinc and manganese oxalates is similarly treated.

J. Meyer and R. Kanters observed that precipitated manganic oxide is more reactive chemically before it has been calcined ; this is shown by its solubility in a soln. of ammonium chloride. M. Berthelot observed that dry manganous iodide burns like tinder when heated in oxygen, forming iodine and manganese hemitrioxide ; and manganous bromide behaves in an analogous manner at a dull red-heat. M. Berthelot found that dry manganous chloride forms the hemitrioxide when heated in dry oxygen ; and D. C. Knab obtained a similar result by heating the chloride in air. According to C. M. Tessié du Motay, when steam is passed over an alkali manganate at 450°, oxygen is given off and a mixture of alkali hydroxide and manganese hemitrioxide remains. O. Michel and E. Grandmougin found that when manganese dioxide is heated in ammonia gas, nitrogen, water, and the hemitrioxide are formed. C. Lepierre observed the formation of the hemitrioxide when manganous carbonate is heated with molten potassium nitrate ; and W. Spring and M. Lucion, when a mixture of barium dioxide and manganous chloride is triturated in a mortar. H. B. Weiser and G. L. Mack prepared an **organosol** of manganic oxide in propyl alcohol.

Braunite occurs massive and also crystalline. The colour is dark brownish-black to steel-grey. W. Biltz discussed the colour of the derivatives of this oxide. W. Haidinger found the crystals to be tetragonal, with the axial ratio $a : c = 1 : 0.9850$, and the habit is octahedral, with the angles nearly isometric ; G. Flink gave $a : c = 1 : 0.99218$. M. J. Schuster regarded the crystals as rhombohedral with a tetartohedral development, but this is doubtful. The (001)-faces of the crystals are faintly striated ; the (221)-faces are uneven and striated ; and the (421)-faces are smooth and even. Twinning occurs about the (101)-plane ; the (111)-cleavage is perfect. M. L. Huggins examined the structure by the X-radiogram method. P. E. Wretblad found that the cubic crystals have $a = 9.391$ A. G. Aminoff, and W. V. Smitheringale discussed the X-radiograms, and the action of various etching reagents. G. A. Thiel also studied the action of various reagents—hydrochloric and sulphuric acids, hydrogen dioxide, and soln. of ferrous and stannous chlorides. The crystals were examined by G. vom Rath, J. Orcel and S. Pavlovitch, A. Schmidt, and G. Flink. C. Drucker and R. Hüttner made some observations on the X-radiograms. W. Zachariasen found the X-radiogram corresponds with the rhombohedron with hexagonal axes of the corundum type of space-lattice with $a = 9.41$; and in *bixbyite*, $(Fe,Mn)_2O_3$, $a = 9.35$ A. The oxygen atoms are distant 2.10 A., and in bixbyite, 2.08 A. P. E. Wretblad gave for the cubic oxide $a = 9.391$ A. The sp. gr. of braunite is 4.75 to 4.82 ; S. Pavlovitch gave 4.81 ; and for the black hemitrioxide C. F. Rammelsberg gave 4.325 ; and K. S. Rao, 4.22 to 4.8. The hardness of braunite is 6.0 to 6.5. S. Pavlovitch found that braunite, in nitrogen at 1190°, formed minute crystals, and at 1400°, in 4 hrs., 2.78 to 3.80 per cent. of oxygen was evolved. E. Jannettaz compared the thermal conductivity in different directions of the crystals, and obtained an isothermal ellipse with an eccentricity of 0.85. P. E. W. Oeberg found the sp. ht. to be 0.1620 between 15° and 99°. If the hemitrioxide be strongly heated, G. Forchhammer, and R. Hermann found that it loses 3.05 to 3.50 per cent. of oxygen and passes into the tritatetroxide. A. Gorgeu, W. Dittmar, W. Biltz, and R. J. Meyer and K. Rötgers made observations on this subject—*vide supra*. A. Simon and F. Feher gave for the heat of formation $4Mn_3O_4 + O_2 \rightarrow 6Mn_2O_3 + 54$ Cals. C. Doelter said that braunite is opaque to the X-rays. W. Flight observed a thermoelectric current. L. L. Fermor found that Indian braunite is magnetic, and if a high proportion of iron is present, the magnetism is strong. K. S. Rao found that braunite is paramagnetic ; and it has an axis of minimum magnetizability. R. D. Harvey examined the electrical conductivity ;

and E. Diepschlag and F. Wulfestieg, the high temp. conductivity of mixtures with magnesia, alumina, and silica. E. Wedekind and C. Horst found the magnetic susceptibility to be 41.99×10^{-6} mass unit. K. S. Rao gave 0.4×10^{-3} for the maximum susceptibility. There is an axis of maximum symmetry with a perpendicular plane in which the susceptibility is independent of orientation. Along the axis of symmetry the susceptibility is a minimum, and in the plane a maximum; the difference is about 2 per cent. K. Honda and T. Sone found that the change of magnetic susceptibility, $\chi \times 10^6$, with temp. undergoes a transition about 933° as manganic oxide passes to manganosic oxide:

	$-184°$	$-90°$	$-4°$	$21°$	$116°$	$388°$	$669°$	$928°$	$990°$
$\chi \times 10^6$.	150·0	99·2	73·0	69·0	58·4	42·9	33·8	27·9	27·7

The hemitrioxide was found by W. Müller to be reduced to manganous oxide by hydrogen at a red-heat; S. Hauser found the reduction occurs between 243° and 262°; and F. Glaser said that at 230° it is reduced by hydrogen to the trita-tetroxide. O. T. Christensen obtained similar results with other reducing agents. For M. Martinon's observations on the action of hydrogen dioxide, *vide infra*, manganese dioxide. O. T. Christensen found that when the oxide is heated with hydrochloric acid, it forms manganous chloride, with the evolution of oxygen; it dissolves in hot, conc. sulphuric acid with the evolution of oxygen, and, according to E. Turner, it also dissolves in boiling, dil. sulphuric acid. K. Thaddéeff found that the native manganese oxides give a violet colour when heated with conc. sulphuric acid diluted with its own vol. of water. P. Berthier observed that with boiling nitric acid part of the manganese passes into soln. as manganous nitrate, and part remains undissolved as manganese dioxide. O. T. Christensen found that when the hemitrioxide is treated with dil. sulphuric or nitric acid, half the manganese passes into soln.; but, according to J. Meyer and R. Kanters, if mercury be present: $Mn_2O_3 + 2Hg + 6HNO_3 = 2HgNO_3 + 2Mn(NO_3)_2 + 3H_2O$. Calcined manganese hemitrioxide is only slightly attacked by acetic acid. W. Heintz found that with phosphoric acid manganous phosphate is formed. W. H. Coghill and J. B. Clemmer studied the soap flotation of the manganese oxides.

In 1772, J. B. L. Romé de l'Isle [2] described the crystals of a mineral which he called *manganaire cristallisée*; and in 1804, R. J. Haüy described it as *manganèse oxyde métalloïde*; while A. G. Werner, L. A. Emmerling, and M. H. Klaproth called it *Graubraunsteinerz*; J. F. L. Hausmann, *Graubraunstein*; D. L. G. Karsten, and C. C. von Leonhard, *Graumanganerz*; A. Breithaupt, *Glanzmanganerz*; C. Hartmann, *Braunmanganerz*; F. A. Quenstedt, *Braunmangan*; F. Mohs, and R. Jameson, *prismatoidal or prismatic manganese ore*; W. Haidinger, **manganite**; F. S. Beudant, *acerdèse*—from ἀκερδής, unprofitable—in allusion to its being of little value as a bleaching agent for glass; and T. Thomson, *newkirkite* from Neukirchen, Alsace. Manganite occurs in Cornwall, Cumberland, Devonshire, and Somerset, England; Aberdeenshire, Scotland; Ross and Dublin, in Ireland; Piedmont, Emilia, Bologna, Ravenna, Scandiano, Tuscany, and Sardinia, Italy; Alemtejo, Portugal; Estremadura, Jaén, Huelva, Aragonia, Ternel, Zamora, and Asturia, Spain; Hautes-Pyrénées, Ariège, Pyrénées-Orientales, Aude, Isère, Vosges, Mayenne, and Basses-Pyrénées, France; Ilefeld, Harz; Ilmenau and Oehrenstock, Thuringia; Undenaes and Längban, Sweden; Christiansand, Norway; Bogoslowsk and Jekaterinburg, Urals; Transcaucasus; Owani, Japan; Cape Colony and French Congo, Africa; Santiago, Cuba; Tarapaca, Chili; Tarma, and Bongara, Peru; Negaunee, Michigan; Douglas Co., Colorado; Nova Scotia, New Brunswick, Gloucester Co., King's Co., and Restigouche Co., Canada; Victoria. Analyses of the mineral by L. Gmelin, E. Turner, C. F. Rammelsberg, A. Gorgeu, C. M. Kersten, V. Sevoz and J. Breuilhs, J. A. Arfvedson, W. H. Hobbs, H. How, C. W. Blomstrand, C. C. von Leonhard, L. C. Beck, G. Dupouy, and F. Kovar correspond approximately with **hydrated manganese hemitrioxide**, $Mn_2O_3.H_2O$, or $H_2Mn_2O_6$. The so-called *manganese ochre* found by G. de Geer in the neighbourhood of Upsala

is an impure hydrated hemitrioxide or tritatetroxide ; and likewise also a deposit found by G. di Boccard in the neighbourhood of Eugania. When the artificial product is dried at 100° B. Franke, and J. Meyer found that it approximates in composition to $Mn_2O_3.H_2O$. H. Laspeyres regarded manganite as a derivative of a hypothetical acid, $H_{10}MnO_8$—namely, $H_4Mn_3MnO_8$ or $2H_2Mn_2O_4$ with bivalent manganese; P. Groth represented it as a derivative of $Mn(OH)_3$ by the loss of water to form $MnO(OH)$, and W. W. Coblentz's observations on the ultra-red spectrum showed that the absorption band of hydroxyl is present but no water bands. C. F. Rammelsberg found that, unlike braunite and hausmannite, manganite is not decomposed by conc. nitric acid, and concluded that it is a true sesquioxide like geothite and diaspore. On the contrary, A. Gorgeu found that boiling nitric acid acts on the finely-powdered mineral, converting half the manganese into manganous nitrate and half into hydrated manganese dioxide ; hence he wrote the formula $MnO.MnO_2.H_2O$. B. Franke also found that the artificial oxide with dil. sulphuric acid forms a manganous salt and hydrated manganese dioxide : $Mn : O_2 : Mn : (OH)_2 + H_2SO_4 = MnSO_4 + H_2O + (HO)_2MnO$, and he therefore regarded it as being constituted with bi- and quadrivalent manganese :

$$Mn{<}^O_O{>}Mn{<}^{OH}_{OH} \qquad \text{\large ◢}$$
M. Sem discussed this subject; and he supposed that there are two classes of manganic salts, distinguished by their colour—violet and brown—but J. Meyer said that this is not right, because manganic salts exist in soln. in various colours—violet, brown, red, dark green, and olive-green ; and the whole of these differently coloured soln. have practically identical absorption spectra. F. Hebler regarded the artificial hydrate—variously written $Mn_2O_3.H_2O$, $MnO_2(HO)_2$, and $HMnO_2$—to be hydrogels ; but F. Wilborn considered natural manganite to be a definite compound.

L. Carius obtained hydrated manganese hemitrioxide by heating to 138° finely-divided, artificial manganese dioxide with conc. sulphuric acid, mixing the soln. of manganic sulphate in sulphuric acid with an excess of water, and washing the resulting precipitate with water. B. Franke obtained it by the action of dil. soda-lye on a soln. of potassium manganic sulphate. It is not certain what are the products obtained by P. Berthier by the action of chlorine, not in excess, on manganous carbonate suspended in water, and by R. Hermann by passing air through a soln. of a manganous salt in ammoniacal ammonium chloride. According to F. Kuhlmann, in a furnace for calcining the residue in the manufacture of chlorine from manganese dioxide and hydrochloric acid, when mixed with limestone, black crystals of manganese tritatetroxide were obtained, which, according to A. des Cloizeaux, are pseudomorphs after manganite. According to C. M. Kersten, crystals of manganite are formed in the thermal springs of Carlsbad ; and, according to R. W. Townsend, and J. Noggerath, they are likewise formed in the thermal springs of Cape Colony. According to A. Anargyros, what was probably **colloidal manganic oxide** was obtained by reducing potassium permanganate by sodium arsenite at 65° to 70°. The brown colloidal soln. can be kept for over a month ; it liberates oxygen from hydrogen dioxide—more rapidly in alkaline than in neutral soln. H. B. Weiser and G. L. Mack prepared an organosol with propyl alcohol.

Manganite occurs in columnar and, more rarely, in granular masses ; it also occurs in stalactic masses, and in crystals which are frequently grouped in bundles. The colour is dark steel-grey or iron-black, and J. L. C. Schröder van der Kolk said that the streak is reddish-brown or black. T. Thomson, and J. F. L. Hausmann found that the colour of thin splinters in transmitted light is sometimes brown. J. Meyer said that when formed by the hydrolysis of manganic cyanide, it is a black, gelatinous mass, which becomes less hydrated when heated with the mother-liquor, and it then changes in colour from black to brown, resembling ferric hydroxide. The colour change is due either to the decomposition of the hydrate or to a change

in the size and physical character of the particles.   J. Meyer and R. Nerlich found that the oxidation of a soln. of manganous chloride made alkaline by ammonia, and mixed with ammonium chloride, is the most convenient way of making manganic oxide—*vide infra*, manganous chloride.   According to W. Haidinger, the rhombic crystals of manganite have the axial ratios $a : b : c = 0.84407 : 1 : 0.54484$.   Contact twinning occurs about the (011)-plane.   There are also cruciform twinning and often repeated twinning with the composition face parallel or inclined, analogous to rutile.   The prismatic crystals may be long and terminated by the (001)-face or by a zone of macropyramids with the planes striated parallel to their mutual intersections.   The prismatic crystals may be short and terminated by the (001)-face with numerous macrodomes or by highly complex macropyramids.   The prismatic faces are deeply striated vertically.   The crystals were described by J. B. L. Romé de l'Isle, R. J. Haüy, W. Phillips, F. Mohs, C. F. Naumann, J. D. Dana, A. Sadebeck, V. Goldschmidt, F. Zambonini, F. Rutley, T. Haege, A. Lévy, K. Busz, R. Brauns, A. Lacroix, G. P. Traverso, P. Groth, A. d'Achiardi, E. Manasse, W. P. Jervis, R. P. Greg and W. G. Lettsom, J. H. Collins, M. F. Heddle, L. H. Borgström, J. Samojloff, A. Raimondi, W. H. Hobbs, G. Rose, S. R. B. Cook and co-workers, etc.   The hemihedral crystals were discussed by P. Groth, W. Haidinger, and A. Sadebeck ; the corrosion figures, by R. Koechlin ; and the isomorphism with diaspore and goethite, by G. Rose, A. Breithaupt, and J. F. L. Hausmann, and with chrysoberyl, by E. Kayser.   G. Flink described rhombic crystals of what he called *sphenomanganite* from Längban, Sweden ; the mineral closely resembles manganite.   The (010)-cleavage of manganite is perfect ; and the (110)- and (001)-cleavages are distinct.   W. H. Zachariasen found that the X-radiogram corresponds with a body-centred space-lattice of the corundum type with $a = 9.41$ A. and the calculated density of 5·00.   W. V. Smitheringale studied the X-radiograms, and also the action of various etching liquids on manganite.   G. A. Thiel also discussed the action of various reagents—sulphuric and hydrochloric acids, hydrogen dioxide, and soln. of ferrous and stannous chlorides.   W. F. de Jong obtained for the space-lattice of manganite $a = 4.46$ A., $b = 5.28$ A., and $c = 2.88$ A.   A. Ferrari and A. Scherillo gave $a = 4.41$ A., $b = 5.19$ A., and $c = 2.83$ A., with 2 mols. of $MnO(OH)$ per unit cell.

The sp. gr. given by C. F. Rammelsberg is 4·335 ; W. Haidinger, 4·312 to 4·338 ; A. Gorgeu, 4·34 to 4·39 ; and E. Manasse, 4·27.   The hardness ranges from 3 to 4.   O. Mügge found that the crystals embedded in sodium nitrate, and at a press. of 4300 kgrms. per sq. cm., suffer a displacement along the (010)- and parallel to the (001)-faces.   The sp. ht., according to H. Kopp, is 0·176 between 20° and 52°.   J. Königsberger found that the extinction coeff. for $\lambda = 0.5$ to 4.0μ is 15 ; for $\lambda = 1.6$ to 4.0μ, 14 ; for $\lambda = 4.0$ to 40μ, 56 ; and for $\lambda = 15$ to 40μ, 78 ; the reflecting power is 0·25 ; and the observed absorption is 200 times greater than the value calculated from the electrical conductivity.   E. S. Larsen gave for the index of refraction $a = 2.24$, $\beta = 2.24$, and $\gamma = 2.53$; J. Orcel and S. Pavlovitch discussed the optical properties of the mineral.   J. Königsberger observed that the birefringence is very strong ; and, added E. S. Larsen, the optical character is negative.   W. W. Coblentz found that no sharp bands occur in the ultra-red transmission spectrum over the region extending to 9μ, but there are faint bands at 3μ (hydroxides) and at 6.2μ.   R. D. Harvey examined the electrical conductivity.   F. Beijerinck found that if manganite is free from pyrolusite, it is a non-conductor of electricity.   K. Honda and T. Sone gave for the magnetic susceptibility of manganic oxide, Mn_2O_3 :

	−184°	−90°	−4°	21°	194°	510°	876°	1100°	1318°
$\chi \times 10^6$.	150·0	99·2	73·0	69·0	53·0	38·4	30·4	27·7	25·4

E. H. Williams discussed the structure of the paramagnetic oxide.   J. R. Blum found that in nature manganite is readily transformed into pyrolusite, hausmannite, and braunite.   J. Meyer and R. Nerlich observed that the acid hydrolysis of man-

ganic salts leads to the formation of manganese dioxide and manganous salt, whilst alkaline hydrolysis merely precipitates manganic hydroxide. By acid hydrolysis, however, probably manganic hydroxide is first formed and at once decomposed, since it is shown that manganic hydroxide is decomposed by dil. mineral acids into manganese dioxide and manganous salt. That manganic hydroxide is a true tervalent manganese compound is probable from the fact that dil. hydrofluoric acid, hydrocyanic acid, and oxalic acid dissolve it completely, to form complex manganic compounds. Conc. sulphuric, selenic, phosphoric, and hydrochloric acids also dissolve it completely, but conc. nitric acid oxidizes it completely to manganese dioxide. K. Fredenhagen and G. Cadenbach studied the action of hydrofluoric acid on the oxide.

L. Carius observed that when manganite is heated in air, it forms manganese tritatetroxide; and A. Gorgeu added that at 300° it forms pseudomorphous manganese dioxide, while braunite remains unchanged. B. Franke found that the artificial crystals lose no water at 120°, but at higher temp. water is given off. N. Kurnakoff and V. Cernych said that a loss of water without the loss of oxygen occurs when manganite is heated to 365°–400°. M. Martinon found that with an acidic soln. of hydrogen dioxide, oxygen is given off and manganous oxide is formed; and in an alkaline soln. manganese dioxide is first formed, which then decomposes the hydrogen dioxide. J. Meyer found that the precipitated manganic hydroxide forms an unstable soln. with conc. hydrochloric acid and a stable soln. with hydrofluoric acid. A. Wagner found that hydrogen sulphide slowly forms manganous sulphide and sulphate, sulphur, and water. J. Meyer and W. Schramm observed that the reaction of sulphur dioxide with manganic hydroxide suspended in water proceeds in two ways, the manganic sulphite first formed decomposing according to the equations $Mn_2(SO_3)_3 = MnSO_3 + MnS_2O_6$, and $Mn_2(SO_3)_3 = MnSO_4 + MnSO_3 + SO_2$; there is no reduction to manganous salts, nor any decomposition of the manganic salt into manganous salts and the dioxide. The solvent action of sulphurous acid was studied by C. W. Davis. According to L. Carius, with conc. sulphuric acid at 100° green manganic sulphate is formed without the evolution of oxygen. H. C. H. Carpenter observed the formation of manganous sulphate and dithionate by the action of sulphurous acid on the hydrated oxide, $Mn_2O_2(OH)_2$. B. Franke observed that the hydrated oxide may be decomposed by hot, conc. sulphuric acid to form manganous sulphate and $MnO_2.H_2O$, as indicated above. L. Carius found that dil. sulphuric acid, cold or gently warmed, does not decompose manganite free from manganous oxide, but if that oxide be present, some manganite may be dissolved. J. Meyer said that precipitated manganic hydroxide forms stable soln. with sulphuric and phosphoric acids. P. Berthier found that manganese hemitrioxide is decomposed by conc. nitric acid, forming manganous nitrate and hydrated manganese dioxide. H. C. Bolton found that manganite is attacked by citric acid less readily than pyrolusite. R. Hermann observed that the hemitrioxide forms a reddish-brown soln. with tartaric acid, and in 24 hrs. the soln. deposits manganous tartrate and forms formic acid and carbon dioxide; oxalic and malic acids are reduced, with the evolution of carbon dioxide, and a manganous salt is formed. Formic, acetic, benzoic, and hippuric acids are without action. E. Reichardt found that when moist manganite mixed with magnesia alba, or alkali carbonate, with or without water, is shaken up with air, a nitrate is formed. J. Meyer and W. Schramm observed that a complex acid is formed with malonic acid. H. von Wartenberg and W. Gurr observed that a eutectic is formed with zirconia.

The hydrated manganese hemitrioxide is supposed to exhibit slight acidic properties in certain minerals. If the compounds of manganese dioxide with the bases be called **permanganites,** the compounds of manganese hemitrioxide with the bases will be called by the unfortunate term **manganites.** H. Credner [3] described a black or brown crystalline mineral, *Kupferhaltiger Manganerz*, from Friedrichsroda, Thuringia. Analyses by H. Credner, and C. F. Rammelsberg agree

with $4(CuO,MnO).Mn_2O_3$. C. F. Rammelsberg called the mineral **crednerite**. H. Laspeyres regarded it as a salt, $Cu_3Mn_3MnO_9$, of the acid $H_{12}MnO_9$. The analyses of a sample from Mendip Hills, Somersetshire, by L. J. Spencer and E. D. Mountain agree with **copper manganite**, $CuO.Mn_2O_3$, or $Cu(MnO_2)_2$. The mineral occurs in Somersetshire in radiating fan-like groups or hemispherical masses of thin, iron-black plates with a bright, metallic lustre. The mineral is perhaps monoclinic, pseudohexagonal by twinning. The cleavages are perfect. The hardness is 4, and the sp. gr. 5·03. H. Credner gave 4·5 to 5·0 for the hardness, and 4·89 to 5·07 for the sp. gr. C. F. Rammelsberg found the sp. gr. to be 4·95 to 4·97. L. J. Spencer and E. D. Mountain found that the mineral dissolves in conc. hydrochloric acid with the evolution of chlorine, but resists attack by nitric acid. A. Gorgeu obtained copper manganite, $CuO.Mn_2O_3$, by heating the tetritamanganite to redness. According to E. A. Schneider, when an ammoniacal cupric oxide soln. is mixed with soda-lye and to the deep blue soln. manganous chloride is added drop by drop, with constant stirring, and the copper oxide and manganic oxides are used in the molecular ratio 1 : 1 or 2 : 1, the whole of the copper is at once removed, but with the ratios 3 : 1 or 4 : 1 or 5 : 1 a portion of the copper remains in soln. The black precipitate thrown down in each case seems to have the composition of **copper tritamanganite**, $3CuO.Mn_2O_3$, although, if an excess of copper soln. is not used, the precipitate approximates **copper hemimanganite**, $2CuO.Mn_2O_3$. The compounds are oxidized by exposure to air. H. Rose appears to have prepared a **silver manganite**, $Ag_4O.Mn_2O_3$, by the action of a warm soln. of manganous sulphate on an excess of moist silver oxide, or adding manganous sulphite to an ammoniacal soln. of silver oxide ; and F. Wöhler, by adding alkali-lye to a mixed soln. of a silver and a manganous salt. H. Rose also reported $Ag_4O.Ag_2O.Mn_2O_3$ to be formed by the action of a cold soln. of manganous sulphate on moist silver oxide. G. Barbieri said that $Ag_4O.Mn_2O_3$ is not formed, but rather a mixture of silver and manganese dioxide.

A. Gorgeu [4] prepared **magnesium manganite**, $MgO.Mn_2O_3$, or $Mg(MnO_2)_2$, by melting a mixture of dried manganese, sodium, and magnesium sulphates in the proportions 3 : 1 : 3. The cold product containing some zincite is washed with hot water, and then allowed to stand for 15 minutes in 5 per cent. acetic acid. The brown, octahedral crystals are probably analogous to hausmannite—*magnesium-hausmannite*. It was also prepared by igniting magnesium tetrapermanganite. G. E. Moore described a mineral from Sterling Hill, New Jersey, and he called it **hetaerolite**—from ἑταῖρος, companion—in allusion to its occurring intimately associated with chalcophanite. It forms botryoidal coatings with a columnar structure. C. F. Naumann called it *hetairite*. J. Orcel and S. Pavlovitch studied the optical properties of the mineral. G. M. Butler called the sample from the Wolftone mine, Leadville, Colorado, *wolftonite*. It contains zinc and manganese and was hence called *zinc-hausmannite*. The formula corresponding with the analysis of W. E. Ford and W. M. Bradley is **zinc manganite**, $ZnO.Mn_2O_3.\frac{1}{2}H_2O$, and from the analysis reported by C. Palache, $ZnO.Mn_2O_3$, or $Zn(MnO_2)_2$. The hardness is 5·5 to 6·0 ; and the sp. gr. given by G. E. Moore is 4·933, that by C. Palache is 4·85, and that by W. E. Ford and W. M. Bradley is 4·6. The index of refraction is over 1·78. E. S. Larsen gave for the tetragonal crystals the indices of refraction $\omega=2·26$ to 2·34, and $\epsilon=2·10$ to 2·14 ; C. Palache gave $\omega=2·35$ and $\epsilon=2·10$. The optical character is negative ; the pleochroism is feeble. E. Divers assumed that $ZnO.Mn_2O_3.nH_2O$ is formed in the working of the Leclanché cell by the action of ammonium zinc chloride on manganese dioxide. A. Gorgeu fused a mixture of manganous, sodium, and zinc sulphates, washed the product with water and dil. acetic acid, and obtained zinc manganite in crystals resembling those of hausmannite ; **cadmium manganite**, $CdO.Mn_2O_3$, was produced by igniting cadmium pentapermanganite. G. Flink reported a **hydrated lead manganite**, $2PbO.Mn_2O_3.H_2O$, at Langban, Sweden. The pitch-black, lustrous mineral was named **quenselite**—after P. Quensel. The monoclinic crystals have the axial ratios

$a : b : c = 0.9767 : 1 : 1.667$, and $\beta = 93.6°$. The basal cleavage is somewhat micaceous and perfect; the streak of the opaque mineral is dark brownish-grey. The sp. gr. is 6·842, and the hardness 2·5. Hausmannite, *manganese tritatetroxide--vide supra*—may be regarded as **manganous manganite**, $MnO.Mn_2O_3$, or $Mn(MnO_2)_2$. According to A. Gorgeu, **cobalt manganite**, $CoO.Mn_2O_3$, is obtained by igniting cobalt hexapermanganite; and **nickel manganite**, $NiO.Mn_2O_3$, from nickel penta-permanganite. M. Rüger also obtained the cobalt salt. The black mineral **lubeckite**, described by J. Morozewicz, occurs at Miedzianka, Poland. The analysis corresponds with the formula for **copper cobaltic manganite**, $4CuO.\frac{1}{3}Co_2O_3, Mn_2O_3.4H_2O$. Its sp. gr. is 4·8, and its hardness 2 to 3. A. Gorgeu observed that when freshly precipitated hydrated manganese dioxide is digested in a hot aq. soln. of cobalt sulphate, part of the manganese is dissolved, and the insoluble product obtained consists of cobalt mangano-cobaltite, which on ignition at a red-heat furnishes a product which is not a mixture of the oxides Mn_3O_4 and Co_3O_4, since the latter is unstable at a red-heat; and it is considered to be **manganous cobaltous cobalti-manganite**, $MnO.CoO.Mn_2O_3.Co_2O_3$.

§ 11. Manganese Dioxide

A. Breithaupt [1] described a light grey manganese oxide—*Graumanganerz*—which he called **polianite**—from πολιός, grey, or πολιαίνεσθαι, to become grey. It is distinguished from pyrolusite by its hardness and its anhydrous character. It occurs at Platten, and Joachimsthal, Bohemia, and in a few other localities. It is comparatively rare. Analyses were reported by C. F. Plattner, C. F. Rammelsberg, S. L. Penfield, A. Gorgeu, and L. L. Fermor. The results agree with the formula for **manganese dioxide,** MnO_2. The colour of polianite is light steel-grey, or iron-grey. J. L. C. Schröder van der Kolk said that the streak is black or grey with a reddish-brown tinge. The mineral occurs in composite parallel groupings of minute crystals having a rough summit and a rhombic form. A. Breithaupt, and R. Köchlin considered that the crystals belong to the rhombic system, but E. S. Dana, and A. Rosati and H. Steinmetz showed that the crystals are tetragonal, and are isomorphous with cassiterite, plattnerite, zircon, and rutile. E. S. Dana gave for the axial ratio $a : c = 1 : 0.66467$, and A. Rosati and H. Steinmetz, $1 : 0.6621$. The crystals are often pseudomorphs after manganite. The (110)-cleavage is perfect. A. Breithaupt gave 4.838 to 4.880 for the sp. gr. ; C. F. Rammelsberg, 5.026 ; and S. L. Penfield, 4.992. The mineral is brittle, and its hardness is 6.0 to 7.0.

The history of the mineral **pyrolusite** has been discussed in connection with that of manganese. The mineral *varvicite*, or *varvacite*, obtained by R. Phillips in Warwickshire, was considered by A. Breithaupt to be intermediate between pyrolusite and manganite. Related minerals were obtained by A. Duflos, and

E. Turner from Ilefeld, Harz; and by P. H. Walker, from Austinville, Virginia. Numerous analyses of pyrolusite have been reported by P. Berthier, J. A. Arfvedson, L. Gmelin, E. Riegel, E. Turner. V. Sevoz and J. Breuilhs, H. Ludwig, T. L. Phipson, I. Domeyko, L. Brackebusch, A. Liversidge, E. F. Smith, D. T. Day, J. L. Jarman, J. and H. S. Pattinson, A. Gorgeu, N. Kozowsky, F. Kovar, C. Rimatori, F. Drake, L. L. Fermor, H. Jimeno, C. A. Tenne and D. S. Calderon, A. Serra, F. Kossmat, G. Dupouy, H. How, C. R. A. Wright and A. E. Menke, M. M. P. Muir, F. T. Teschemacher and J. D. Smith, M. Scheffler, A. Schwarzenberg and A. Engelhardt, J. B. J. D. Boussingault, etc. The results range from 77·60 to 83·56 per cent. MnO; 3·13 to 17·90 per cent. O_2; 0 to 0·50 per cent. CaO; 0 to 2·31 per cent. BaO; 0 to 0·1 per cent. MgO; 0 to 3·0 per cent. $(K,Na)_2O$; 0 to 0·50 per cent. PbO and CuO; 0 to 0·22 per cent. NiO; 0 to 0·27 per cent. CoO; 0 to 0·91 per cent. Al_2O_3; 0 to 4·31 per cent. Fe_2O_3; 0 to 2·21 per cent. SiO_2; 0 to 0·1 per cent. SO_3; 0 to 0·5 per cent. P_2O_5; and 0·50 to 5·0 per cent. H_2O. Traces of lithium, zinc, silver, bismuth, thallium, indium, rare earths, arsenates, and fluorine have also been reported. P. Askenasy and C. L. Rényi, H. Bischoff, and H St. C. Deville and H. Debray found nitrates present; R. J. Kane, chlorides; A. Kundert, silver; F. Wöhler, thallium; and C. Huber, vanadium. The results agree with those required for a more or less impure manganese dioxide, MnO_2 or $MnO_2.nH_2O$. E. Donath and H. Leopold discussed pyrolusite and its applications.

H. Heymann found that in nature pyrolusite occurs in pseudomorphs after manganite, calcite, and rhodochrosite; while J. R. Blum observed pseudomorphs after dolomite and smithsonite. E. Döll, S. von Szentpetery, W. Haidinger, and V. Lenher discussed this subject. T. Schlösing obtained manganese dioxide by heating manganese nitrate between 150° to 195°; F. Kuhlmann recommended 200°; and A. Gorgeu added that if the nitrate be slowly decomposed at 155° to 162°, the product is crystalline and resembles polianite. The same product is obtained in the presence of manganese chloride or sulphate, or of the nitrates of calcium, strontium, barium, magnesium, potassium, and sodium, for these products can afterwards be washed away from the crystalline dioxide. If ferric nitrate be present, the manganese dioxide will be contaminated by ferric oxide. C. R. A. Wright and A. E. Menke obtained the crystalline dioxide by heating a mixture of manganese and potassium nitrates, and washing the alkali salt away from the cold product. P. Berthier, G. J. Young, and G. Wischin also obtained the dioxide by calcining the nitrate. F. Göbel, and H. Moissan prepared the dioxide by heating to 300° a mixture of manganous carbonate with twice its weight of potassium chlorate. According to J. B. Hannay, when a conc. nitric acid soln. of a manganous salt is warmed in the presence of crystals of potassium chlorate, the whole of the manganese is precipitated as manganese dioxide; and if a salt of iron is present, the precipitate is a complex manganate of iron and manganese, $2Fe_2(MnO_4)_3.Mn(MnO_4)$. $12H_2O$, or $Fe_2(MnO_4)_3.MnO_2.6H_2O$. The manganese dioxide precipitated in the absence of iron appears as a black mass of crystalline plates which under the microscope are steel-grey. The thinner plates are transparent and purplish-red. They are free from water. F. Beilstein and L. Jawein used a similar process. C. R. A. Wright and A. E. Menke were unable to prepare the anhydrous dioxide from the hydrated dioxide either by standing it over conc. sulphuric acid or by heating it to 200°. Oxygen is slowly evolved at 210°. A. Gorgeu, however, found that nearly all the water can be slowly driven off at 200°. W. A. Whitesell and J. C. W. Frazer said that specially active manganese dioxide for catalytic reaction can be prepared (a) by the decomposition of potassium permanganate with conc. nitric acid; (b) by treating E. Frémy's oxide with conc. nitric acid, diluting, and washing; (c) by the oxidation of manganous sulphate with potassium permanganate in nitric acid soln.; and (d) by the oxidation of precipitated manganous hydroxide. J. Meyer and R. Kanters prepared hydrated manganese dioxide by passing sulphur dioxide into a soln. of potassium permanganate at 75°, and washing

the precipitate with dil. sulphuric acid and water. When dried at 100° to 105°, the composition is $MnO_2.H_2O$, and when heated to 200° to 225°, some oxygen is lost, but the water content is not reduced below 3·74 per cent. Methods were also described by S. Kaneko and co-workers, D. J. Brown and R. F. Tefft, and Y. Kato and T. Matsuhashi. Y. Kato and K. Yamamoto heated the lower oxides with 3 to 5 per cent. of an alkali hydroxide or carbonate in air or oxygen at 500°, and washed the ground product with water and then with dil. acid. For the electrolytic process, *vide infra*, the hydrated dioxide.

Pyrolusite is iron-black or dark steel-grey, occasionally with a bluish tinge. The mineral usually occurs massive and granular, with reniform coats. It is commonly columnar. The crystals are usually pseudomorphs after manganite. According to E. C. Harder, pyrolusite occurs associated " with psilomelane, either lining or filling cavities in it, or occurring in alternating layers with it in botryoidal masses. In such masses, it consists of numerous parallel needles arranged perpendicularly to the faces of the layers." The association of pyrolusite with psilomelane indicates that this pyrolusite is an alteration product of that mineral. In 1892, J. D. Dana said that it was not definitely known whether pyrolusite was an independent mineral species with a crystalline form of its own, or only a secondary mineral derived chiefly from the dehydration of manganite or the hydration of polianite. A. St. John, however, found that the X-radiogram of polianite agrees with a space-lattice having a body-centred tetragonal array of MnO_2-groups with an axial ratio $a : c = 1 : 0.651$; edge, 4·44 A.; and density, 5·043. The oxygen atoms lie on a face-centred tetrahedral lattice and the manganese on a body-centred lattice, a manganese atom being at the centre of alternate tetrahedra of oxygen atoms. Since the pattern of pyrolusite is similar, any external form leading to its classification as rhombic is due to pseudomorphism. A. Ferrari also obtained a tetragonal lattice with $a : c = 1 : 0.625$, $a = 4.865$ A., and $c = 3.284$ A.; sp. gr. 5·27; and said that the supposed rhombic form of pyrolusite is pseudomorphous. Polianite, pyrolusite, and the artificial dioxide have the same tetragonal space-lattice. V. M. Goldschmidt gave for the space-lattice of the rutile type $a = 4.41$ A., $c = 2.88$ A., and $a : c = 1 : 0.6525$. Some observations were made by C. Drucker and R. Hüttner, M. L. Huggins, and J. E. L. Jones and B. M. Dent. W. V. Smitheringale discussed the X-radiograms, and also the action of various etching liquids; G. A. Thiel also studied the action of various reagents on the mineral—sulphuric and hydrochloric acids, hydrogen dioxide, and soln. of ferrous and stannous chlorides. The crystals were discussed by W. Haidinger, W. H. Miller, A. Gorgeu, A. Breithaupt, R. Köchlin, J. D. Dana, etc. A. F. Rogers attributed the fibrous character of pyrolusite to its occurrence as a pseudomorph, but E. T. Wherry and T. L. Watson said that the fibres are sometimes the result of primary crystallization and not pseudomorphous after manganite. E. Turner gave 4·819 for the sp. gr. of pyrolusite; V. Sevoz and J. Breuilhs, 4·81; S. L. Penfield, 4·732 to 4·858; A. Gorgeu, 4·75 to 5·10; L. Playfair and J. P. Joule, 4·81; L. L. Fermor, 4·47 to 4·94; A. Breithaupt, 4·838 to 4·880; C. F. Rammelsberg, 5·026; J. D. Dana, 4·732 to 4·858; and J. L. Jarman, 4·69. J. B. Hannay gave 4·935 for the artificial crystals. Pyrolusite is much softer than polianite, having a hardness between 2 and 3; R. Köchlin found that it has soft and hard parts, so that when the powder is rubbed on glass, some granules may scratch the glass.

F. Richarz represented manganese dioxide by the formula $O=Mn=O$. H. Laspeyres regarded manganese dioxide as a manganous manganate, $Mn(MnO_4)$, but F. Beijerinck considered that in such a case the electrical conductivity should be smaller than what it is. A. Guyard regarded the dioxide as a permanganate, $3MnO.Mn_2O_7$, that is, $(MnO_2)_5$. W. Spring and M. Lucion do not recommend the simple formula $MnO.MnO_3$, but favour that based on A. Guyard's hypothesis. C. W. Eliot and F. H. Storer represented the dioxide as a basic manganic manganate, $Mn_2O_3.MnO_3$, that is, $(MnO_2)_3$; and B. Franke supposed the hydrate $3MnO_2.2H_2O$ to be a polymanganic acid: $(HO)_2Mn=O_2=Mn=O_2=Mn(OH)_2$. R. T. Colgate

said it is more than probable that manganese dioxide is not simple, but consists of complexes of the type $(MnO_2)_n$, in which the value of n is at least 4 and may well be some multiple of this. The eight oxygen atoms in the complex may be pictured as so packed that they form a cube, each of four faces of which contains in addition a single manganese atom, the four atoms being in one plane. Such an arrangement is formulated in the following figure, with circles for oxygen atoms and black discs for manganese atoms. Freshly precipitated manganese dioxide is slightly soluble in a conc. soln. of hydrogen dioxide, cooled to $-20°$, and the resulting soln. gives off oxygen at ordinary temp. Hence, G. Bredig and A. Marck suggest that the soln. contains a true manganese superoxide,
$$Mn{<}^O_O \qquad or \qquad Mn{<}^O_O \qquad .$$
isomeric with ordinary manganese dioxide, $O{=}Mn{=}O$. J. Orcel and S. Pavlovitch discussed the optical properties of polianite ; and W. Biltz, the colour of the derivatives of the oxide. According to W. Biltz, the fact that natural manganese dioxide always contains basic oxide points to its acidic nature—**manganous acid.** Treatment of manganese dioxide containing water with liquid ammonia removes all the water except 1 mol. Moreover, the existence of the compounds $(NH_4)_2MnO_3$ and NH_4HMnO_3 is indicated by the isothermal decomposition of the ammoniate.

W. Spring said that when the dioxide is subjected to a high press. it takes on a metallic lustre. As indicated below, O. Sackur and E. Fritzmann calculated from the electrochemical data the **dissociation pressure** $6·3 \times 10^{-23}$ atm. at $18°$. The low value here obtained agrees with the ready oxidation of manganous hydroxide in air. Observations were also made by E. Moles and M. Crespi. C. Zengelis observed a discoloration on silver suspended over manganese dioxide in a closed vessel ; this is taken to indicate a slight vaporization at ordinary temp. P. Berthier found that at dull redness manganese dioxide loses oxygen to form manganese hemitrioxide, and at a higher temp. it forms the tritatetroxide. When heated in oxygen, E. R. Schneider said that the hemitrioxide is formed ; and W. Dittmar found that when heated by a bunsen burner in dry oxygen, air, or nitrogen, the hemitrioxide is formed ; but at about $660°$, in air, nitrogen, or in vacuo, the trita-tetroxide is produced. J. B. Hannay observed that at a red-heat, in oxygen, the dioxide passes into the tritatetroxide. C. R. A. Wright and A. P. Luff added that the evolution of oxygen from finely crystalline pyrolusite begins at $390°$; and A. Geuther stated that when heated to bright redness, manganese monoxide is formed. H. Moissan found that in the electric arc furnace the dioxide rapidly melts, bubbles with the evolution of oxygen, and passes into the monoxide. C. Schubert, and W. Hempel and C. Schubert said that decomposition begins between $470°$ and $500°$, and is ended at $1280°$. These observations are not all concordant. The work of R. J. Meyer and K. Rötgers, and W. Biltz on the thermal decomposition of the dioxide has been discussed in connection with manganese hemitrioxide and tritatetroxide—*vide supra* ; the decomposition begins at $530°$ in air, and at $565°$ in oxygen. J. Meyer and R. Kanters observed that some oxygen is lost at $200°$ to $230°$. P. Askenasy and S. Klonowsky found that when the dioxide is heated in vacuo for 24 hrs. at $230°$ and another 2 hrs. in dry oxygen at $400°$, it exhibits the following press., p mm., of oxygen at different temp. :

	$382°$	$406°$	$448°$	$478°$	$536°$
p . .	23	(77)	125	200	>1040

The observed press., 77 mm., at $406°$ is too high, and was obtained by absorption, which is very slow at that temp. The observations of R. J. Meyer and K. Rötgers were made upon a form of dioxide first heated to $500°$, which attains equilibrium very slowly, and the results, in consequence, are not reliable. P. Askenasy and

S. Klonowsky represented these results for the reaction $2Mn_2O_3+O_2\rightarrow4MnO_2$ by log $p=-24944/4\cdot571T+1\cdot75$ log $T+0\cdot001446T+2\cdot8$. S. Klonowsky's curve is shown in Fig. 48. F. Bahr and O. Sackur found a dissociation press. of 816 mm. at 572°. R. J. Meyer and K. Rötgers found that the reaction $4MnO_2$ $=2Mn_2O_3+O_2$ begins in air at 530°, and in oxygen at 568°. H. Saito studied the effect of heating manganese dioxide in air. C. Drucker and R. Hüttner found that the dissociation press. depends on the physical state of the dioxide; with compact masses the press. was 125 mm. at 530°, and with fine powder, 125 mm. at 450°. It is supposed that the MnO_2 and Mn_2O_3 form a solid soln., but since the isotherms are not constant it is assumed that the solid soln. is formed in definite layers, which to some extent protect the interior from decomposition. The X-radiograms of the products agree that Mn_2O_3 is formed in the thermal decomposition of manganese dioxide. The dissociation press., p mm., of the artificial dioxide is:
FIG. 48.—Dissociation Pressures of Manganese Dioxide.

	410°	450°	548°	586°	616°	652°	668°
p . .	2	5	40	109	235·5	268	763

A. Simon and F. Feher measured the dissociation press. of the dioxide, and observed breaks just over 600° corresponding with the formation of Mn_2O_3, and near 1000° corresponding with the formation of Mn_3O_4. M. Blumenthal observed the formation of no compound between MnO_2 and Mn_2O_3 below 850° in the thermal dissociation of manganese dioxide. H. von Jüptner calculated for the dissociation press., p atm., in the reaction $MnO_2=Mn+O_2$, log $p=-27418T^{-1}+1\cdot75$ log $T+2\cdot8$; and for $2MnO_2=2MnO+O_2$, log $p=-11667T^{-1}+1\cdot75$ log $T+2\cdot8$ (vide infra, MnO), and

Products	600°	1000°	1400°	1800°	2200°	2400°
p { Mn .	$0\cdot0_{38}9230$	$0\cdot0_{19}4285$	$0\cdot0_{11}5265$	$0\cdot0_{6}1839$	$0\cdot0_{3}1536$	$0\cdot0_{2}1955$
MnO .	$0\cdot0_{11}1648$	$0\cdot0_{3}2415$	$0\cdot9378$	$103\cdot5$	2218	7130

G. Spezia said that pyrolusite melts in the oxidizing blowpipe flame to form a black enamel. H. Kopp gave 0·159 for the **specific heat** between 17° and 48°; and A. S. Russell found the mean sp. ht., c, and the mol. ht., C, to be:

	−78° to −188°	0° to −78·2°	48·3° to 2·4°
c . .	0·0978	0·1407	0·1642
C . .	8·50	12·23	14·27

The results fit W. Nernst and F. Lindemann's equation fairly well. R. W. Millar found the **molecular heat** of manganese dioxide to be:

	−200·2°	−189·6°	−180·1°	−177·4°	−124·2°	−73 5°	−23 2°	20 8°
C_p .	3·901	5·370	8·858	6·406	7·996	10·35	12·19	13·53

The results are plotted in Fig. 30. There is a marked discontinuity between 87·743° K. and 98·437° K. J. Maydell studied the mol. ht. M. Berthelot calculated from H. le Chatelier's observations on the **heat of formation** $(Mn,O_2)=125\cdot3$ Cals.; $(MnO,O)=30\cdot4$ Cals. O. Sackur and E. Fritzmann gave $(MnO,O)=19\cdot6$ Cals.; H. von Jüptner, $Mn+O_2=MnO_2+125\cdot3$ Cals.; and $2MnO+O_2=2MnO_2+53\cdot32$ Cals.; C. Drucker and R. Hüttner gave 26 Cals. for the decomposition of manganese dioxide into Mn_3O_4, and R. J. Meyer and K. Rötgers, $4MnO_2=2Mn_2O_3+O_2-50\cdot8$ Cals.; A. Simon and F. Feher obtained for the change $4MnO_2\rightarrow2Mn_2O_3+O_2$, 26 Cals.; M. Blumenthal gave log $p=Q/4\cdot6T+1\cdot75$ log $T+2\cdot8$ for the heats of dissociation, Q, and obtained 37·1 Cals. for pyrolusite; 27·9 Cals. for amorphous and 28·5 Cals. for crystalline manganese dioxide; and W. G. Mixter gave (Mn,O_2) $=119\cdot6$ Cals. J. C. W. Frazer and C. E. Greider made observations on this subject.

They gave $MnO_2 \rightarrow MnO(+O) = -7.0$ cals.; $1.5MnO_2 \rightarrow 0.5Mn_3O_4(+O) = -23.2$ cals. R. W. Millar gave 13·93 for the **entropy** ; −42·6 for the change of entropy in the reaction $Mn+O_2=MnO_2$, and −122,600 cals. for the change of **free energy.** J. Thomsen gave $(Mn,O_2,H_2O)=166.33$ Cals.; and $Mn(OH)_2+O=MnO(OH)_2$ (or $MnO_2.H_2O)+21.56$ Cals. P. Askenasy and S. Klonowsky calculated for the heat of the reaction $2Mn_2O_3+O_2 \rightarrow 4MnO_2$, 24,944 cals. J. Ewles found that the dioxide exhibits a faint cathodoluminescence. G. Fournier studied the absorption of β-rays ; and O. Stelling, the K-series of X-rays. C. Doelter observed no coagulation of the colloid in radium rays. F. Beijerinck found that pyrolusite is a better electrical conductor than polianite, and in contact with metals acquires an electric charge. The subject was discussed by R. D. Harvey. F. Streintz observed that the **electrical conductivity** of a cm. cube of the compressed powder is 0·16 mho at 0° ; and M. le Blanc and H. Sachse, 10^{-2} mho, at 20°. P. Fischer examined the electrical conductivity of mixtures of manganese dioxide with copper oxide, lead dioxide, and potassium bromide. E. W. von Siemens and J. G. Halske found that electrodes— anodes—can be made from compressed manganese dioxide. A. A. Somerville found that the electrical resistance is 10,000,000 ohms at 120° and 70 ohms at 1100°. T. W. Case observed no change in the electrical conductivity on exposure to light. Measurements of the **electrode potential** of manganese dioxide were made by C. Wheatstone, W. Beetz, H. Buff, F. M. Raoult, R. B. Clifton, W. H. Preece, K. Schreber, L. Kahlenberg, and W. A. Smith. According to J. K. H. Inglis, a platinum electrode coated with manganese dioxide and immersed in an acidic soln. of a manganous salt changes in accord with $MnO_2+4H^{\cdot} \rightleftharpoons Mn^{\cdot\cdot}+2H_2O+2F$, in which these are the intermediate stages : $MnO_2+2H^{\cdot} \rightleftharpoons Mn^{\cdot\cdot}+H_2O+\frac{1}{2}O_2$ and $\frac{1}{2}O_2+2H^{\cdot} \rightleftharpoons H_2O+2F$; or else $MnO_2+4H^{\cdot} \rightleftharpoons Mn^{\cdot\cdot\cdot\cdot}+2H_2O$ and $Mn^{\cdot\cdot\cdot\cdot} \rightleftharpoons Mn^{\cdot\cdot}+2F$. Both hypotheses give the same results for the oxidation potential, namely, $\epsilon=\epsilon_0 +(RT/2F)$ log $([H^{\cdot}]^4/['Mn^{\cdot\cdot}])$ volt, where ϵ_0 represents the potential when the $H^{\cdot}$ and $Mn^{\cdot\cdot}$ concentrations of the soln. are unity. With cells of the type $MnO_2 : MnSO_4,H_2O : KCl_{sat. soln.} : 0.1N$-$KCl,Hg_2Cl_2 : Hg$, at room temp., ϵ_0 can be calculated from the degree of ionization of the electrolyte, when $\epsilon_0=E-(0.058/2)$ log $(C^4_{H^{\cdot}}/C_{Mn^{\cdot\cdot}})$, when C denotes the concentrations of acid and manganous salt in mols per litre, E volt is the observed potential, and ϵ_0 volt the normal potential referred to the $0.1N$-calomel electrode, at room temp. :

$C_{Mn^{\cdot\cdot}}$	.	0·01	0·001	0·0001	0·01	0·001	0·0001
$C_{H^{\cdot}}$	.	0·05	0·05	0·05	0·005	0·005	0·005
E	.	0·935	0·958	0·986	0·821	0·851	0·874
ϵ_0	.	0·993	0·987	0·986	0·995	0·996	0·990

Hence, the oxidation potential against the decinormal calomel electrode is nearly 1·00 volt, or 1·35 volt against the normal hydrogen electrode. O. F. Tower found similar values of ϵ_0 for dil. nitric acid soln. of manganous nitrate and dil. sulphuric acid soln. of manganous sulphate. J. Scobai obtained for manganese dioxide in N-H_2SO_4, 0·628 volt against a normal mercurous sulphate electrode ; with the dioxide in $12N$-H_2SO_4, 0·752 volt ; in $22N$-H_2SO_4, 0·93 volt ; and in conc. H_2SO_4, 1·1 volt. R. C. Wells found the potential of pyrolusite against N-KCl to be 0·93 volt ; D. J. Brown and H. A. Liebhafsky gave 1·236 volts for the oxidation potential of the reaction $MnO_2+4H^{\cdot}+2e \rightleftharpoons Mn^{\cdot\cdot}+2H_2O$ in soln. of perchloric acid. S. Popoff and co-workers were unable to measure the potential of the permanganate-hydrogen- manganese dioxide electrode ; and the manganese dioxide-hydrogen-manganous electrode was irreversible, nor could a value be calculated from the potentials of manganese dioxide electrodes. C. E. Ruby found the electrode potentials : $MnO_2+4OH' +2F =MnO_4''+2H_2O-0.664$ volt ; $MnO_2+4OH'+3F =MnO_4'$ $+2H_2O-0.647$ volt ; and $MnO_2+2H_2O+3F =MnO_4'+4H^{\cdot}-1.757$ volts, at 25°. D. J. Brown and R. F. Tefft found that from e.m.f. measurements of the cell $H_2|HClO_4(m_1)|HClO_4(m_2),KMnO_4(m_3)|MnO_2$, at 25°, the oxidation potential of the reaction $MnO_4'+4H^{\cdot}+3e=MnO_2+2H_2O$ was found to be 1·586 volts. This value decreases with decreasing acid concentration exactly as required by theory.

Pure manganese dioxide could not be obtained electrolytically. C. Drucker and R. Hüttner studied the e.m.f. of the cells Pt|Mn dioxide, electrolyte | sat. soln. KCl|N-KCl, HgCl|Hg, where the electrolyte was sulphuric acid and manganous sulphate or monochloracetic acid, manganous sulphate, and 0·1N-NaOH. They calculated $-0·79$ volt for the change $Mn_2O_3+6H^{\cdot}+2\oplus\rightarrow2Mn^{\cdot\cdot}+3H_2O$. It is inferred that the manganese dioxide passes into manganic oxide and not into manganosic oxide, as supposed by K. Arndt and co-workers. Observations were also made by J. K. H. Inglis, W. A. Smith, C. E. Ruby, Y. Kato and T. Matsuhashi, S. Popoff and co-workers, and O. Sackur and W. Taegener.

O. F. Tower found that the conc. of the H·-ions in a soln. at a manganese dioxide electrode has about four times as much influence on the e.m.f. as the conc. of the Mn··-ions. T. J. Martin and A. J. Helfrecht's results for the electrode potentials of manganese dioxide—artificial with 82·5 per cent. MnO_2; and natural ore with 67·5, 74·8, and 88·9 per cent. MnO_2—are summarized in Fig. 49. L. Kahlenberg and A. S. McDaniel found the oxidation potential depends on the nature of the solvents, being less in basic solvents than in water or in neutral solvents. The electrode potential of manganese dioxide in water is $-0·978$ volt; in acetone, $-1·137$ volts; in pyridine, $-0·698$ volt; and in amylamine, $-0·476$ volt. The presence of a little water has a great effect in the case of acetone, but for pyridine and amylamine the effects increase slowly as the quantity of water increases, so that the constant for water is attained when from 90 to nearly 100 per cent.

FIG. 49.—The Effect of the H·-ion Concentration on the Electrode Potential of Manganese Dioxide.

of water has been added. When sulphuric acid is used instead of a soln. of lithium chloride, the e.m.f. rises from $-0·978$ to $-1·566$ volts.

W. Hähnel measured the concentration of the iodine formed in the reaction $MnO_2+4H^{\cdot}+2I'\rightleftharpoons Mn^{\cdot\cdot}+2H_2O+I_2$. The results were erratic, owing (i) to the solubility of iodine in a 1·1 mol. soln. of manganous chloride, being $6·23\times10^{-3}$ when its solubility in water is $3·7\times10^{-3}$ mol per litre, showing that some combination occurs ; and (ii) to the oxidation of iodide to iodate by the manganese dioxide when the conc. of the iodine ions is small enough to permit of the existence of measurable quantities of iodate ions. Equilibrium is attained very slowly. From these imperfect results, the normal oxidation potential of manganese dioxide works out to be greater than 1·2 volts when referred to the normal hydrogen electrode. The potential which just deposits manganese dioxide from a soln. of manganese sulphate depends on the acidity of the soln. The results show that $\epsilon_0=E-0·0295\log([H^{\cdot}]^4/[Mn^{\cdot\cdot}])$ gives $\epsilon_0=1·35$ volts nearly. Analogous results were obtained with a bromide in place of iodide. When chlorine is passed into a neutral or faintly acid soln. of manganese chloride, the dioxide is precipitated. It is found that in a 0·22N-soln. of manganous chloride, precipitation occurs when the conc. of the hydrogen ions is 0·0101, and does not occur when it is 0·013 mol per litre. This result leads to a value of about 1·57 volts for the normal potential of manganese dioxide, but in calculating this the formation of manganic chloride in the soln. is neglected, the effect of which is to make the calculated value too large. O. Sackur and E. Fritzmann found the e.m.f. of the combination: oxygen at one atm. press. | sat. soln. MnO | MnO_2 | Pt, in which the reaction is $2MnO+O_2=2MnO_2$,
to be 0·32 volt. This gives $6·3 \times 10^{-23}$ atm. for the dissociation press. of manganese dioxide at 18°. H. A. J. Wilkens and H. B. C. Nitze discussed the magnetic separation of pyrolusite; F. Daniels, H. D. Holler and L. M. Ritchie, B. M. Thompson, K. Fischbeck and E. Einecke, W. C. Phalen, R. Hüttner, C. Drotschmann, K. Arndt and co-workers, C. Drucker, A. Keller, J. Meyer and R. Kanters, V. P. Ilinsky and N. P. Lapin, S. Kaneko, N. S. Krivolutskaya and G. G. Morozoff, V. A. Kostjejeff, and E. Divers discussed the action of manganese dioxide in Leclanché cells; and P. Fischer, the conductivity of mixtures of cupric oxide and manganese dioxide.

E. T. Wherry found pyrolusite to be a fair **radio-detector**; and C. Tissot constructed a sensitive detector from pyrolusite and a metal. The combination acts without an auxiliary current, so that its activity does not depend on a change of resistance, and it is supposed to be a thermoelectric effect produced by the electric waves. R. Bunsen placed pyrolusite beyond bismuth in the **thermoelectric series**. E. Wedekind and C. Horst gave $14·58 \times 10^{-6}$ mass unit for the **magnetic susceptibility** of the dioxide at 14°. and S. Meyer gave 27×10^{-6} mass unit at 17°. Observations were also made by P. Hausknecht, and G. Grenet. F. Stutzer and co-workers gave 128×10^{-6} for the coeff. of magnetization. G. Wistrand gave $37·3 \times 10^{-6}$ mass unit for the magnetic susceptibility. K. Honda and T. Sone plotted the magnetic susceptibility, $\chi \times 10^6$, with temp. and observed irregularities on the curve corresponding with the transformations: $MnO_2 \rightleftharpoons Mn_2O_3$ at 525°; $Mn_2O_3 \rightleftharpoons Mn_3O_4$ at 933°; and $Mn_3O_4 \rightleftharpoons MnO$ at 1160°. The results up to 535° are :

	−186°	−106°	−3°	21°	111°	396°	527°	535°
$\chi \times 10^6$.	74·9	49·9	39·9	38·4	33·7	24·0	22·8	25·9

A. F. Benton found that no **helium** is adsorbed by manganese dioxide between −79° and 184°. According to W. Müller, G. Forchhammer, E. Turner, and M. Ravack, **hydrogen** reduces manganese dioxide to the tritatetroxide at 202°; C. R. A. Wright and A. P. Luff found that pyrolusite begins to be reduced at 190°; F. Glaser, that the dioxide is reduced to the hemitrioxide at 183°; and L. Benedek, that pyrolusite passes first into the hemitrioxide, then into the tritatetroxide at 280°, and finally into the monoxide. S. Hauser said that reduction occurs between 230° and 245°. According to H. Moissan, hydrogen at 230° reduces the dioxide to the hemitrioxide, if more strongly heated, to the tritatetroxide, and at 280°, to the monoxide; while E. Newbery and J. N. Pring found that the dioxide is reduced to metal by hydrogen at 2000° and 150 atm. press. H. Saito, and J. C. W. Frazer and C. E. Greider studied the heat of reduction by hydrogen of manganese dioxide. A. de Hemptinne found that there is a slow reduction of manganese dioxide by hydrogen at ordinary temp. and press., and the product quickly re-oxidizes in air. A. F. Benton studied the adsorption of hydrogen and of **oxygen** by manganese dioxide and found that at −79°, 0°, and 25° respectively 0·070, 0·11, and 0·039 c.c. of hydrogen at n.p. θ are adsorbed per gram, and that at 25° and 110° respectively 0·234 and 0·085 c.c. of oxygen at n.p. θ are adsorbed per gram. The actions of **air**, and oxygen are indicated above. J. L. Odier said that when manganese dioxide is heated in air, nitrogen oxides are produced. P. Askenasy and E. L. Rényi obtained also these oxides at 280°, and more at a higher temp., not exceeding 700°. The oxides are also produced in an atm. of carbon dioxide, and the nitrogen oxide is derived from the manganese dioxide itself, which contains 0·002 per cent.—*vide supra*, nitrates in manganese dioxide. O. Brunck found that the dioxide can be heated above 320° in an atm. of **ozone** and oxygen, but not in air or carbon dioxide. The dioxide does not act on **water**. W. C. Bray and H. D. Draper, C. E. Lanning, and H. W. Foote and J. K. Dixon studied the adsorption of water by the dioxide. A. Gorgeu found that pyrolusite has no action on litmus paper, but F. von Kobell added that some varieties, after calcination, have an alkaline reaction. According to L. J. Thénard, a soln. of

hydrogen dioxide loses all its active oxygen when in contact with manganese dioxide without the latter losing any oxygen. G. Bredig and R. M. von Berneck found that the action of one part of manganese dioxide in 10,000,000 parts of soln. is appreciable. A. Geuther, and B. C. Brodie said that some manganese dioxide is reduced in the presence of acids, and A. Baumann represented the reaction : $MnO_2+H_2O_2=MnO+H_2O+O_2$. A. Gorgeu found that the manganese dioxide remains intact if the hydrogen dioxide is slightly alkaline, but if slightly acidic, a little manganese dioxide is reduced. Hydrated manganese dioxide prepared in the cold decomposes hydrogen dioxide and at the same time is reduced to an extent depending on the proportion of hydrogen dioxide employed. The limit at which hydrogen dioxide has no action on manganese dioxide is represented by the basic manganite $MnO_2.2MnO.\frac{1}{4}H_2O$, which can be obtained by the prolonged action of a current of air on manganous hydroxide suspended in its own mother-liquor. Since hydrogen dioxide reduces only the oxides above this limit, it would seem that the oxidizing action of the dioxide on manganous hydroxide ought to cease at the same point. This, however, is not the case ; the manganous hydroxide can be oxidized even to a higher degree than the acid manganite $MnO_2.MnO$. The decomposition of hydrogen dioxide is more rapid in presence of a strong base, and the oxidation of the manganese is at first partly determined by the influence of the basic function of the manganous hydroxide, assisted afterwards by the acid function of the dioxide which is formed. The higher oxidation may be regarded as due to the action of nascent oxygen. M. Martinon found that in a strongly acidified soln. a mol of hydrogen dioxide gives a mol of oxygen and at the same time the manganese dioxide is reduced to the monoxide ; but in alkaline soln. a mol of hydrogen dioxide gives a gram-atom of oxygen and the manganese dioxide remains unchanged. The results with manganese tritatetroxide and hemitrioxide are similar. G. Tammann found that a trace of silver sulphate accelerates the rate of decomposition. The reaction was studied by A. Lottermoser and R. Lehmann, A. von Kiss and F. E. Lederer, F. Wöhler and A. Geuther, L. Swiontkowsky, G. Bredig and A. Marck, A. Marck, E. Schöne, M. Martinon, R. Engel, T. Gigli, B. C. Brodie, A. Carnot, and S. M. Tanatar. G. Bredig and A. Marck found that in the decomposition of hydrogen dioxide by colloidal manganese dioxide, in conc. alkaline soln., the rate of decomposition diminishes rapidly with the conc. of the alkali. Substances such as hydrogen sulphide, hydroxylamine, mercuric cyanide, potassium cyanide, iodine, carbon monoxide, and mercuric chloride, which act as " poisons " in the decomposition of hydrogen dioxide by colloidal metals, exert no depressing influence on the activity of manganese dioxide. On the other hand, sodium hydrophosphate reduces appreciably the rate of the reaction, and this is attributed to the formation of manganese phosphates. In the presence of mercuric chloride the hydrogen dioxide is more rapidly decomposed, and this is probably due to the simultaneous action of the colloidal mercury which is formed by reduction of the mercuric chloride by the hydrogen dioxide, in which reaction, also, the colloidal manganese dioxide acts as a catalyst. In the absence of free alkali no catalytic decomposition is observed, and the soln. obtained in these circumstances is quite colourless. In the further investigation of the cause of the disappearance of the brown colour, it has been found that freshly-precipitated manganese dioxide dissolves to an appreciable extent in conc. hydrogen dioxide soln. cooled to $-20°$. At the ordinary temp. the resulting soln. evolves oxygen very readily. It is supposed that a manganous salt of hydrogen dioxide is present in the colourless soln. ; this salt—*vide supra*—$Mn\big\langle{\!\!\!\begin{smallmatrix}O\\ \text{III}\\ O\end{smallmatrix}}$, is isomeric with manganese dioxide, $Mn\big\langle{\!\!\!\begin{smallmatrix}O\\ O\end{smallmatrix}}$.

In the so-called *oxygen bath* produced by adding a mixture of perborate and permanganate to the bath water, hydrogen dioxide and colloidal manganese dioxide are produced, and the latter catalyzes the decomposition of the former, producing a supersaturated soln. of oxygen, which is liberated in small bubbles on the skin of the bather. The effect of electrolytes in the bath water on the evolution of oxygen

is so marked that it led A. Lottermosei and R. Lebmann to investigate the influence of various salts on the decomposition of hydrogen dioxide by manganese dioxide at 30°. The reaction is very sensitive to accidental impurities, and also the velocity depends on the order in which the reagents are added to the water in which the reaction takes place. The assumption that the increase in the velocity constants is to be explained by the formation and subsequent decomposition of a hydrogen dioxide salt could not be confirmed. The influence of the cations of the added salts, which all have the same anion, follows the lyotropic series $Ba\cdots>Sr\cdots>Ca\cdots>Na\cdot>K\cdot>Li\cdot$, in which $Ba\cdots$ accelerates the reaction to the greatest extent and $Li\cdot$ retards it the most. At higher concentrations, barium falls after calcium. $Mg\cdots$ and $NH_4\cdot$, on account of the reduction of the conc. of the hydroxyl ion which they produce, strongly retard the reaction.

When manganese dioxide suspended in hot alkali-lye is treated with **chlorine,** alkali permanganate is formed. The reaction proceeds more quickly with the hydrated dioxide. L. E. Rivot and co-workers found that the reaction does not occur at a low temp. ; at 0° a dark brown substance is formed ; and at 15° to 20° the product is dark green. F. P. Venable and D. H. Jackson found that the dioxide is chlorinated at 460° by a mixture of chlorine and carbon monoxide. According to M. Berthelot, the hydrohalide acids undergo complex reactions, liberating respectively chlorine, bromine, and iodine. O. Ruff and H. Krug found that **chlorine trifluoride** reacts with manganese dioxide with incandescence. G. Gore, and O. T. Christensen observed that manganese dioxide is very sparingly soluble in **hydrofluoric acid,** and that it does not dissolve in the water-free acid. K. Fredenhagen and G. Cadenbach studied the action of this acid. According to G. Gore, dry liquid **hydrogen chloride** whitens manganese dioxide without the evolution of gas or dissolution ; and R. E. Hughes found that the dry gas attacks the dry dioxide. M. Berthelot observed that cold **hydrochloric acid** dissolves manganese dioxide, with the evolution of some chlorine and the formation of a dark brown soln. containing manganese trichloride or tetrachloride or a complex of the tetrachloride and hydrogen chloride —*vide infra* ; when heated, the reaction is symbolized : $MnO_2+4HCl \rightleftharpoons MnCl_2 +2H_2O+Cl_2$; while a mixture of alkali chloride and sulphuric acid forms manganese sulphate and chlorine. V. Dolejsek and J. Heyrovsky observed that the higher chloride of rhenium or dwimanganese passes over with the chlorine. According to T. Schlösing, a mixture of hydrochloric and nitric acids forms chlorine and manganous nitrate. C. W. Hempel, M. M. P. Muir, and W. Hähnel found that dil. sulphuric acid and **potassium iodide** react with the dioxide, liberating iodine. According to G. Vortmann, C. L. Müller and G. Kircher, C. W. Hempel, and E. Pollacci, the **chlorides** furnish chlorine only in the presence of strong acids— *e.g.* sulphuric acid ; the **bromides** give bromine in the presence of weak acids— *e.g.* acetic acid ; and the **iodides** yield iodine in the presence of the weakest of acids—*e.g.* carbonic acid. M. M. P. Muir found that the velocity of the reaction between manganese dioxide and hydrochloric acid is much accelerated in the presence of potassium iodide. A. Baudrimont observed that the m.p. of **potassium chlorate** is lowered by the presence of manganese dioxide, and the decomposition of the salt is accelerated without forming intermediate perchlorate. The reaction was studied by H. M. McLaughlin and F. E. Brown, F. E. Brown and co-workers, O. Brunck, W. Spring and E. Prost, E. Jungfleisch, G. J. Fowler and J. Grant, A. Wagner, E. Wiederhold, A. Vogel, F. Bellamy, H. N. Warren, G. Krebs, C. F. Schönbein, J. C. Poggendorff, M. E. Chevreul, J. C. G. de Marignac, C. H. L. von Babo, W. R. E. Hodgkinson and F. K. S. Lowndes, H. MacLeod, E. J. Mills and G. Donald, W. H. Sodeau, Y. Kato and T. Matsuhashi, and V. H. Veley—*vide* 1. 8. 7.

J. A. Arfvedson found that when manganese dioxide is heated with **sulphur,** sulphur dioxide and manganous sulphide are formed. A. Wagner, and E. Donath observed that iron-free pyrolusite decomposes **hydrogen sulphide,** forming a sulphide which, in a current of carbon dioxide, gives off hydrogen sulphide, but retains a little sulphur. According to A. de Hemptinne, manganese dioxide rapidly absorbs

hydrogen sulphide from a mixture of this gas with hydrogen, manganese sulphides being formed. The absorption is much more rapid than with dry hydrogen sulphide alone, although in presence of moisture this gas is readily absorbed by manganese dioxide. E. Priwoznik found that yellow **ammonium polysulphide** at 100° forms green manganous sulphide ; while E. Donath and F. Müllner found that when the dioxide is boiled with **metal sulphides** a thiosulphate is formed. R. E. Hughes observed no reaction between dry **sulphur dioxide** and dry manganese dioxide ; but J. Meyer and W. Schramm observed that when the dioxide is suspended in water, two reactions occur, according to the equations $2MnO_2+4SO_2$ $=Mn_2(SO_3)_3+SO_3=MnSO_4+SO_2+MnS_2O_6$ and $MnO_2+SO_2=MnSO_4$; the latter is favoured and the former repressed by increase of temp. E. J. Russell and N. Smith said that manganese dioxide does not react with sulphur dioxide, but, according to D. L. Hammick, if the manganese dioxide be finely divided, inter-action occurs at dull redness, with the evolution of light and heat. The reddish-brown powder which is formed contains manganese sulphate and one or both of Mn_2O_3 and Mn_3O_4. With a prolonged heating, manganous sulphate is formed— *vide* sulphur dioxide. The reaction was also studied by J. Meyer, J. Meyer and W. Schramm, and T. S. Dymond and F. Hughes—*vide* sulphur dioxide. A. Over-beck, J. Meyer, and J. J. Welter and J. L. Gay-Lussac found that manganese dioxide dissolves in an aq. soln. of sulphur dioxide, forming manganous sulphate and dithionate (*q.v.*). C. W. Davis studied the solvent action of sulphurous acid. F. J. Otto observed that **ammonium sulphite** in ammoniacal soln. reduces the dioxide to the monoxide. According to G. Scurati-Manzoni, **zinc, aluminium, and chromic sulphites** react with hydrated manganese dioxide to form manganous sulphate and the corresponding hydroxide. According to H. Hess, and L. Carius, when manganese dioxide is heated with conc. sulphuric acid to 110°, one-fourth of the oxygen is evolved and manganic sulphate is formed : $2MnO_2+3H_2SO_4=Mn_2(SO_4)_3+3H_2O+O$; and if heated more vigorously, another fourth of oxygen is given off and manganous sulphate is formed : $Mn_2(SO_4)_3=2MnSO_4+SO_3+O$. According to P. Berthier, F. Jones, F. Göbel, E. Donath, and C. R. Fresenius and H. Will, the dioxide does not dissolve in dil. sulphuric acid, except in the presence of organic substances—*e.g.* oxalic acid or sugar—which take up the peroxidic oxygen. K. Thaddéeff found that boiling **sulphuric acid** does not acquire a colour such as is obtained with braunite. C. R. A. Wright and A. E. Menke found that the artificial dioxide produces no coloration when in contact with cold sulphuric acid for 24 hrs. ; and H. A. von Vogel, and C. F. Schönbein observed the formation of manganic sulphate when the dioxide is in contact with cold sulphuric acid—*vide infra* for the action of mercury on the reaction. For the adsorption of acids by manganese dioxide, and the weak basic properties of the dioxide, *vide infra*, the action of hydrogen on potassium permanganate. E. Bamberger found that at ordinary temp. **mono-persulphuric acid** decomposes manganese dioxide with the evolution of ozonized oxygen ; and M. Traube said that the hydrated dioxide forms manganese sulphate and free oxygen when it dissolves in **persulphuric acid ;** under these conditions the anhydrous dioxide is not reduced. A. Seyewetz and P. Trawitz observed that when the dioxide is boiled with a soln. of **ammonium persulphate,** violet per-manganate is produced—the coloration is so sensitive that 1 : 100,000 parts of manganese can be detected. According to W. Schmid, and A. Laugier, **selenious acid** forms selenic acid as it reduces manganese dioxide ; and L. Marino and V. Squin-tana found that some manganous selenite, $Mn(SeO_3)_2$, is formed.

A. F. Benton found that at 25°, 110°, and 184° respectively 0·301, 0·081, and 0·038 c.c. of **nitrogen** at n.p. θ are adsorbed per gram of manganese dioxide. F. Kuhl-mann, and O. Michel and E. Grandmougin found that when manganese dioxide is heated in a current of **ammonia,** the reaction can be symbolized : $6MnO_2+2NH_3$ $=N_2+3Mn_2O_3+3H_2O$, and if the temp. be higher, some nitrous fumes are pro-duced. N. Smith added that in the presence of manganese dioxide, aq. ammonia

forms nitrites and nitrates when exposed to air. G. Leoncini and C. Pieri found that **ammonium salts** are not oxidized by manganese dioxide at ordinary temp. According to E. Divers, soln. of **ammonium chloride** in the presence of certain metals—*e.g.* zinc—are decomposed by manganese dioxide ; hydrogen is given off and some metal passes into soln. C. Drotschmann found that in the Leclanché cell, abnormal amounts of manganese were found in the electrolytes in which artificial pyrolusite was used, although the dissolution of manganese did not appear to be a direct consequence of the depolarizing action of the manganese dioxide. The enhanced chemical action of the artificial variety caused a greater attack on the zinc. The development of free ammonia in the electrolyte of a cell when kept for 14 days was greater when the zinc electrode was completely immersed than when it was partly exposed to the air. Less hydrogen was developed by a cell containing artificial manganese dioxide than by one containing the natural product when kept on open circuit. F. Fischer and F. Bangert observed that at 800° to 1000° **methane** reacts with the oxide, forming a carbide. A. Purgotti found that the dioxide reacts with an acid soln. of **hydrazine sulphate** in accord with $2MnO_2+N_2H_4.H_2SO_4+H_2SO_4=2MnSO_4+4H_2O+N_2$; and with a neutral soln. in accord with $2MnO_2+2(N_2H_4.H_2SO_4)+H_2O=2MnSO_4+4H_2O+N_2$ $+N_2H_4.H_2O$. E. J. Cuy and co-workers studied the reaction. H. Goldberg found that when the dioxide is heated with **potassium azide,** potassium manganate is formed. P. Sabatier and J. B. Senderens found that at 400° **nitric oxide** reduces manganese dioxide to the hemitrioxide. H. A. Auden and G. J. Fowler observed that at ordinary temp. a basic nitrate is slowly produced by nitric oxide ; the action is faster at a higher temp. According to G. Kastner, and C. F. Schönbein, nitric oxide in the presence of water acts on the dioxide, forming manganous nitrite, and if a large excess of dioxide be present, manganous nitrate. P. Sabatier and J. B. Senderens observed that **nitrogen peroxide** forms a nitrate. With **nitrous acid,** manganous nitrate is formed. According to P. Berthier, F. Jones, F. Göbel, E. Donath, and C. R. Fresenius and H. Will, the dioxide does not dissolve in **nitric acid** unless an organic substance is present—*e.g.* oxalic acid or sugar—which takes up the peroxidic oxygen—*vide infra* for the action of mercury on the reaction. H. Bornträger found that manganese dioxide readily dissolves in **nitrosylsulphonic acid.** F. Wöhler found that when manganese dioxide is heated with **sodium nitrate,** in the absence of air, the nitrate is completely decomposed, but no manganate is formed ; but in air, J. G. Gentele found that sodium manganate is produced. F. Kuhlmann added that impure pyrolusite is more active than the pure dioxide. According to J. W. Gatehouse, in the presence of manganese dioxide **ammonium nitrate** decomposes between 165° and 200°, in accord with : $MnO_2+4NH_4NO_3=Mn(NO_3)_2+8H_2O+3N_2$—alone, the ammonium nitrate decomposes at 215°. L. C. A. Barreswil showed that when the dioxide is heated with syrupy **phosphoric acid,** or with an **alkali phosphate,** violet manganic phosphate is produced. A. Michaelis observed no reaction occurs between **phosphorus trichloride** and manganese dioxide at 200°. L. C. A. Barreswil found that **arsenic acid** forms manganic arsenate when it is heated with manganese dioxide, and at a higher temp. oxygen is evolved. C. Reichard found that **arsenious acid** is oxidized by manganese dioxide in alkaline soln. at 50°.

The dioxide is reduced to the metal (*q.v.*) by **carbon** at a high temp. G. Tammann and A. Sworykin said that the reaction with sugar charcoal starts at 460°, and with graphite at 550° ; and that $2MnO_2+C_{amorphous}=2MnO+CO_2+26.6$ Cals. H. Bähr and F. Fallböhmer observed that the addition of manganese dioxide to coal favours the reactivity of the resulting coke as a catalyst in the reaction $C+CO_2=2CO$. Confirmatory results were obtained by J. H. Jones and co-workers. H. S. Taylor and co-workers discussed the activation of manganese dioxide as a catalyst by chromic oxide. I. L. Bell observed that at about 420° manganese dioxide is reduced to the monoxide by **carbon monoxide ;** with pyrolusite, C. R. A. Wright and A. P. Luff found that the reaction begins at about 87°, and

no carbonate is formed. H. Saito studied this reaction; and W. A. Whitesell and J. C. W. Frazer, H. S. Taylor, and A. F. Benton found that at −79°, 0°, and 25° respectively 6·92, 1·90, and 1·26 c.c. at n.p. θ of carbon monoxide are adsorbed per gram. H. Tropsch and A. von Philippovich, J. A. Almquist and W. C. Bray, W. M. Hoskins and W. C. Bray, W. C. Bray and G. J. Doss, H. D. Draper, B. Neumann and co-workers, H. A. J. Pieters, E. J. Witzemann, and W. E. Kuentzel studied the catalytic effect of manganese dioxide on the oxidation and decomposition of carbon monoxide, etc., and W. P. Yant and C. O. Hawk, on the oxidation of methane. F. Merck and E. Wedekind, and E. Baur studied the action of the catalyst *hopcalite*—MnO_2 : CuO=60 : 40 per cent.—on the oxidation of carbon monoxide. C. E. Lanning, and A. F. Benton studied the adsorption of carbon monoxide and of **carbon dioxide** by manganese dioxide and found that at 0°, 25°, 100°, and 184° respectively 8·66, 6·17, 1·20, and 0·12 c.c. of the carbon dioxide at n.p. θ are adsorbed per gram; and H. W. Foote and J. K. Dixon showed that water retards the adsorption of carbon dioxide by manganese dioxide. P. Sabatier and A. Mailhe discussed the catalytic effect of manganese dioxide in the dehydration of ethyl alcohol; and H. D. Draper, the pore vol. of the dioxide as a catalyst. J. C. W. Frazer and C. E. Greider studied the heats of reduction of manganese dioxide by carbon monoxide. T. Bergman found that pyrolusite is attacked by water with carbon dioxide in soln. L. Hackspill and R. Grandadam observed that manganese dioxide is partially reduced by **sodium cyanide** to the metal when heated at 570° to 700° in vacuo; and A. Kutzelnigg, that the powder oxidized a soln. of **potassium ferrocyanide**, possibly—in part—by adsorbed oxygen. H. W. Foote and J. K. Dixon studied the adsorption of **benzene** vapour by manganese dioxide. J. W. Döbereiner found that when manganese dioxide is warmed with **alcohol** and sulphuric acid, aldehyde and other products are formed; and A. Baudrimont found that with **ethylsulphuric acid,** aldehyde is formed. J. C. W. Frazer and C. E. Greider studied the heat of oxidation of carbon monoxide by manganese dioxide. A. Brighenti observed that manganese dioxide acts catalytically in oxidizing methyl, ethyl, and propyl alcoholic soln. of the corresponding alcoholates, and also the vapours of these **alcohols.** C. Matignon and R. Trannoy found that manganese dioxide acts like platinum in accelerating the oxidation of **ether.** H. C. Bolton found that the dioxide is decomposed by citric acid in the cold, readily so when heated—$9MnO_2+10H_8C_6O_7$ $=9MnH_6C_6O_7+13H_2O+6CO_2$; **oxalic acid** acts more quickly. K. Schröder observed that some of the reduced oxide may be re-oxidized by atm. oxygen. According to A. Skrabal, the reaction between oxalic acid and manganese dioxide is similar to that with potassium permanganate. The reaction between permanganate and oxalic acid takes place in the following stages: (*incubation period*) (1) $C_2H_2O_4+KMnO_4\rightarrow Mn^{\cdots}+CO_2$ (measurable); (2) $C_2H_2O_4+Mn^{\cdots}\rightarrow Mn(OH)_2+CO_2$ (practically instantaneously); (*induction period*) (3) $Mn(OH)_2+KMnO_4\rightarrow Mn^{\cdots}$ (less quickly than the former stage); (4) $Mn^{\cdots}$ $+C_2H_2O_4\rightarrow Mn(OH)_2+CO_2$ (practically instantaneously); (5) $Mn^{\cdots}+C_2H_2O_4$ $\rightarrow[Mn(OH)_3.C_2H_2O_4]$ (practically instantaneously); (6) $2Mn^{\cdots}\rightarrow Mn(OH)_2+Mn(OH)_4$ (practically instantaneously); (*end period* I); (7) $[Mn(OH)_3.C_2H_2O_4]\rightarrow Mn^{\cdots}$ (measurable); (8) $C_2H_2O_4+Mn^{\cdots}\rightarrow Mn(OH)_2+CO_2$ (practically instantaneously); (*end period* II); (9) $Mn(OH)_2+Mn(OH)_4\rightarrow 2Mn^{\cdots}$ (less quickly than the former stage); (10) $C_2H_2O_4+Mn^{\cdots}\rightarrow Mn(OH)_2+CO_2$ (practically instantaneously). The rate of stage (1) increases with increase of amount of acid present. Stage (4) is conditioned by the rate at which the ions $Mn^{\cdots}$ are formed in stage (3). In the presence of manganese sulphate the incubation period is not observed, whilst the measurable reaction in the induction period proceeds very quickly. If the conditions for the formation of complex manganic salts are favourable, that is, if the concentration of oxalic acid is great and that of hydrogen ions small, stage (5) proceeds more quickly than any other stage in the induction period, and the end period is expressed by (7) and (8). Otherwise, stage (6) is the most rapid in the induction period

and the end period is expressed by (9) and (10). A. Skrabal and J. Preiss obtained analogous results with **formic acid.** D. Talmud and N. M. Lubman found that the flotability of manganese dioxide in **oleic acid** or mixtures of oleic acid and ammonia is a maximum when $p_H=7$. G. Bruni and C. Pelizzola found that colloidal manganese dioxide causes raw **caoutchouc** to become tacky by catalytic oxidation. W. Thomson and F. Lewis studied its action on **indiarubber.** W. E. Adeney noted the reduction of the dioxide to manganous carbonate by bacterial fermentation. The decomposition of the dioxide by dil. sulphuric or nitric acid in the presence of oxalic acid or **sugar** was studied by P. Berthier, F. Jones, and C. R. Fresenius and H. Will. G. Leoncini and C. Pieri found that manganese dioxide is incapable of oxidizing **organic nitrogen** at ordinary temp.; ammonium compounds are not oxidized; fatty amides are oxidized to nitric acid in boiling aq. soln., with or without acid or alkali, but not below 30°; but amino-acids and purine-derivatives are not oxidized.

L. Kahlenberg and W. J. Trautmann observed that when a mixture of powdered **silicon** and manganese dioxide is heated over the bunsen burner, a sudden glowing occurs, and at a higher temp. reduction occurs. According to G. Rauter, when **silicon tetrachloride** is heated with the dioxide, chlorine, silica, and manganous chloride are formed. F. Knapp found that pyrolusite dissolves in molten **glass** as manganous oxide and oxygen is evolved; on cooling the oxide crystallizes out; if an excess of soda be added, and the mass extracted with sulphuric acid, manganosic oxide remains. Manganese dioxide is used as a bleaching agent for glass— *vide supra.*

L. Franck found that the dioxide is readily reduced by **aluminium** at a high temp. V. Shuleikin and X. Solovova studied the liberation of heat in the thermite reaction with aluminium. J. Meyer and R. Kanters found that neither manganese dioxide nor **mercury** dissolves in cold, dil. sulphuric or nitric acid, yet together they dissolve readily: $MnO_2+2Hg+4HNO_3=Mn(NO_3)_2+2HgNO_3+2H_2O$ by a kind of coupled reaction. With sulphuric acid: $2MnO_2+3Hg+3H_2SO_4=2MnSO_4 +HgSO_4.Hg_2O+3H_2O$. If a 25 per cent. soln. of ammonium, calcium, or magnesium chloride is used in place of acid, the mercury is dissolved, although to a much smaller extent, in the form of mercuric chloride.

F. de Carli found that mixtures of **cuprous oxide** and manganese dioxide begin to react at 350°; no reaction was observed with **cupric oxide.** G. N. Lewis found that the decomposition of **silver oxide** is accelerated by manganese dioxide. D. Balareff said that **barium oxide** reacts vigorously with manganese dioxide below 300°, with the evolution of much heat. Barium oxide containing a trace of water reacts with manganese dioxide at 240°, but **calcium oxide** does not do so below 930°. F. de Carli found a mol of barium, **strontium oxide,** or calcium oxide mixed with 1, 2, or 3 mols of manganese dioxide begins to react at 150° to 250°. No reaction was observed with **magnesium, zinc, or cadmium oxide; stannous oxide** begins to react at 180°; but no reaction was observed with **lead oxide** or **chromic oxide.** In general, R. Böttger showed that manganese dioxide or its hydrate behaves as an oxidizing agent. Thus, H. A. von Vogel, J. W. C. Harvey, and C. Schorlemmer and T. E. Thorpe showed that it oxidizes **stannous chloride** to stannic chloride. A. Gorgeu found that unlike the hydrated dioxide, the neutral and dry dioxide is not hydrated by contact with soln. of **alkali hydroxide.** O. Dieffenbach found that pyrolusite is difficult to hydrate in this way, but if heated with alkali-lye under press., hydration occurs. G. Forchhammer, E. Mitscherlich, W. Spring and M. Lucion, T. Monticelli and N. Covelli, P. F. Chevillot and W. F. Edwards, C. W. Eliot and F. H. Storer, and N. Beketoff found that when manganese dioxide is heated with potassium hydroxide in the absence of air, potassium manganate and manganese hemitrioxide are formed: $3MnO_2=MnO_3+Mn_2O_3$—*vide infra.* C. Binks and J. Macqueen, C. Taquet, and J. Townsend observed that when the dioxide is heated with **magnesium chloride,** chlorine, magnesia, and manganous chloride are produced: $MnO_2+2MgCl_2=MnCl_2+Cl_2+2MgO$. Hydrated man-

ganese dioxide exhibits acidic properties; A. Gorgeu, and J. M. van Bemmelen found that it reddens litmus, it takes up alkalies, and alkaline earths from soln., it liberates carbon dioxide from carbonates, and it imparts an acidic reaction to neutral soln. of salts of the alkalies, alkaline earths, and silver. Hydrated manganese dioxide exhibits basic properties, which are rather feeble. It forms salts- – **permanganites.** For compounds with various bases, *vide infra*, the permanganites. H. N. Morse found that a neutral soln. of **potassium permanganate** is reduced by manganese dioxide; the soln. remains neutral, and all the alkali goes into the precipitate—*vide infra*, potassium permanganate. The reaction was studied by F. W. Skirrow. A. Gorgeu observed that the hydrated dioxide, if of a high degree of purity. does not decolorize a soln. of potassium permanganate.

P. Berthier,[2] A. Gorgeu, and J. Volhard prepared **hydrated manganese dioxide,** approximating $MnO_2.H_2O$, or **manganese oxydihydroxide,** $MnO(OH)_2$, by repeatedly boiling manganous oxide or hydroxide or one of the oxides between manganese monoxide and dioxide with conc. nitric acid. When the wash-water is no longer acidic, the hydrated oxide is peptized to form a brown fluid which is not flocculated by filtration, by shaking, or by standing for a long time; but the addition of an acid, ammonia, or electrolyte coagulates the dispersed solid. G. Forchhammer heated manganous carbonate in air to 260°, and extracted the remaining manganous oxide or carbonate with hot nitric acid or cold, dil. hydrochloric acid. The nearest approach to MnO_2 obtained by W. Reissig was by heating the carbonate for 3 hrs. at 300°. The hydrated dioxide is also produced when a manganous salt is treated with an oxidizing agent. For example, B. C. Brodie, and C. Friedheim treated manganous hydroxide with an alkaline soln. of hydrogen dioxide. The reaction is the basis of a process by P. Jannasch and co-workers for the separation of manganese and zinc in ammoniacal soln. by the addition of hydrogen dioxide, when the manganese is precipitated as $MnO(OH)_2$. The process was examined by A. J. Walker and W. Farmer. A. Mailfert, and L. Maquenne precipitated hydrated manganese dioxide with ozone; and M. Geloso, and G. von Knorre, with ammonium persulphate. The subject was discussed by H. Baubigny, A. Carnot, E. Donath and R. Jeller, M. Dittrich, M. Dittrich and C. Hassel, and F. M. Raoult. According to O. Dieffenbach, native oxides which are attacked with difficulty by alkali-lye are readily hydrated if heated under press. P. Berthier passed an excess of chlorine through water holding in suspension finely-divided manganous carbonate, and extracted the unconverted carbonate from the product by cold, dil. nitric acid, or, according to A. Gorgeu, by boiling with at least 10 per cent. nitric acid. F. J. Otto found that the product of the action of chlorine is the hydrated dioxide, but that the subsequent treatment with nitric acid reduces some of the dioxide. R. Phillips, V. Eggertz, C. R. Fresenius, E. and B. Klimenko, J. Post, A. Gorgeu, R. Böttger, J. Pattinson, J. Volhard, C. Meineke, and E. M. Dingler used sodium or calcium hypochlorite as oxidizing agent; and C. R. A. Wright and A. W. Menke, S. G. Simpson, and G. C. Winkelblech, bromine. C. F. Rammelsberg obtained the hydrated dioxide as a black precipitate by allowing a soln. of manganous bromate to stand for a short time. Mixtures of a chlorate and nitric acid were used for the oxidation by F. Beilstein and L. Jawein, J. B. Hannay, A. Carnot, W. Hampe, A. P. Ford, F. A. Gooch and M. Austin, R. Mackintosh, and G. C. Stone. According to W. W. Fisher, when the dark brown liquid obtained by dissolving manganese dioxide, hemitrioxide, or tritatetroxide in cold, conc. hydrochloric acid is diluted with a large proportion of water, it soon deposits a brown precipitate of the hydrated dioxide. S. U. Pickering, however, found that the composition of the precipitate from manganese trichloride soln. and from the brown soln. prepared by W. W. Fisher ranged from $16MnO_2.5MnO$ to $36MnO_2.5MnO$, or from $11MnO_2.5Mn_2O_2$ to $31MnO_2.5Mn_2O_3$. C. R. A. Wright and A. E. Menke also observed that if the original dioxide contains alkali the precipitate also contains alkali. C. F. Schönbein, and J. M. van Bemmelen found that soln. of manganese tetracetate or disulphate quickly decompose, depositing the hydrated dioxide.

B. Franke found that a soln. of potassium manganic sulphate in dil. sulphuric acid, quickly formed a precipitate of hydrated dioxide, which was quickly filtered, washed successively with water, alcohol, and ether, and dried.

The hydrated dioxide was prepared by E. Mitscherlich by boiling a soln. of potassium manganate or permanganate with an excess of sulphuric, nitric, or oxalic acid ; he represented the composition of the precipitate by $MnO_2.H_2O$; and when dried over conc. sulphuric acid, C. F. Rammelsberg, and T. Morawsky and J. Stingl represented the composition by the formula $3MnO_2.2H_2O$; E. Frémy represented the air-dried precipitate by $10MnO_2.MnO.22\frac{1}{2}H_2O$; and A. Lumière and A. Seyewetz, by $2MnO_2.H_2O$; C. R. A. Wright and A. E. Menke gave for the composition of products dried for some months over conc. sulphuric acid : $K_2O.27MnO_2.2MnO.8H_2O$, and $K_2O.32MnO_2.2MnO.22H_2O$, and J. M. van Bemmelen studied the adsorption of alkalies by the colloidal product. Hydrated manganese dioxide is also a product of the action of many reducing agents on soln. of potassium permanganate, but T. Morawsky and J. Stingl, and C. R. A. Wright and A. E. Menke found that the product always contained some alkali—say $K_2O.8MnO_2.3H_2O$. N. C. H. Schjerning boiled a soln. of potassium permanganate with a mixture of sodium trisulphide and thiosulphate ; T. Macalpine reduced an alkaline soln. of potassium permanganate with acetylene ; A. Steopoe, with

TABLE I.—ACTIVE OXYGEN IN THE PRODUCTS OF THE REDUCTION OF POTASSIUM PERMANGANATE (O : MnO)

Reducing agent	1 per cent. $KMnO_4$ soln.		0·1 per cent $KMnO_4$ soln.

ethylene ; and W. Spring and G. de Boeck treated a soln. of the permanganate with sodium thiosulphate. M. Gröger examined the action of different reducing agents on acidic and neutral soln. of potassium permanganate, and represented the number of atoms of active oxygen per mol. of MnO in the product—Table I. According to M. Geloso, in the titration of soln. of potassium permanganate with $0·1N$-sodium arsenite, within a certain range of concentration of sulphuric acid, the manganese oxide is reduced to Mn_3O_5 ; in neutral soln., or with insufficient acid, a brown turbidity or a yellow coloration is obtained, whilst an excess of acid gives a pink soln., the corresponding states of oxidation of the manganese ranging continuously from MnO_2 through Mn_6O_{11} and Mn_3O_5 to Mn_2O_3. The end-point is similar with certain concentrations of nitric acid, but never in presence of tartaric or phosphoric acids. The degree of oxidation of the manganese at the end-point is affected considerably by Ag·-ions, less by AsO_4'-ions, whilst in presence of Mn··-ions the reduction proceeds quantitatively to MnO_2. The variation in composition of the reduction product with various conditions proves that the formulæ Mn_3O_5 and Mn_6O_{11} do not represent definite compounds, the green liquid being a colloidal soln. of MnO_2 with other substances adsorbed. This sol has a wide absorption band extending to 4900 A., and it polarizes the light it scatters. A similar colloidal soln. is obtainable by adding sulphuric acid to a soln. containing permanganate

and arsenite and diluting the product. The hydrated dioxide is also formed when a soln. of potassium permanganate is treated with a manganous salt. G. Forchhammer used a mixture of 2 mols of the permanganate and 3 mols of the manganous salt in dil. soln. : $3MnCl_2 + 2KMnO_4 + 2H_2O = 2KCl + 4HCl + 5MnO_2$. This reaction was found by A. Gorgeu to occur when a manganous salt is gradually added to a soln. of the permanganate and the liquid neutralized by calcium carbonate ; when the permanganate is added to the soln. of manganous salt, precipitation is complete when 2 mols of the permanganate have been added to 4 mols of the manganous salt : $4MnCl_2 + 2KMnO_4 + 3H_2O = 2KCl + 6HCl + 5MnO_2.MnO$, and if more permanganate be added the reaction progresses : $3(5MnO_2.MnO) + 2KMnO_4 + 2HCl = 2KCl + 20MnO_2 + H_2O$ without the evolution of chlorine or of oxygen. When conc. soln. are used, F. Jones represented the reaction : $2MnCl_2 + 2KMnO_4 = 2Mn_2O_3 + 2KCl + Cl_2 + O_2$. Observations were also made by A. Guyard, J. Volhard, J. Meyer and R. Kanters, C. Meineke, C. Winkler, C. G. Särnström, R. Schöffel and E. Donath, N. Wolff, W. Hampe, W. Spring and M. Lucion, R Habich, T. Morawsky and J. Stingl, and C. R. A. Wright and A. E. Menke. These observers noted the adsorption of alkali by the precipitate, and A. Gorgeu observed that some of the precipitated hydrated dioxide seems to be reduced by the nitric or permanganic acid. O. T. Christensen recommended gradually adding 180 grms. of manganous acetate in two litres of warm water, acidified with acetic acid, to a warm soln. of 79 grms. of potassium permanganate in 1500 c.c. of water. The precipitate was washed by decantation with warm water. E. Krause hydrated pyrolusite by heating it for 8 hrs. with soda-lye at 235° under 8 atm. press. ; and Y. Kato and T. Matsuhashi obtained $MnO_2.H_2O$ by oxidizing the lower oxides with oxygen, using sodium hydroxide as catalyst. D. N. Ghosh obtained the hydroxide as a rhythmic precipitate.

C. Luckow obtained hydrated manganese dioxide by the electrolysis of a dil., feebly-acid soln. of a manganous salt—say the acetate or nitrate—free from chlorides. With a feeble current the anodic deposit has the composition $MnO_2.H_2O$. C. F. Boehringer, A. C. Becquerel, M. Berthelot, N. W. Fischer, A. Classen, A. Classen and M. A. von Reis, A. Riche, A. Brand, C. Engels, J. Köster, A. Piccini, K. Elbs, F. W. Skirrow, E. Frei, L. Schucht, F. Rüdorff, A. P. Rollet, C. N. Otin and E. Grave, the Badische Anilin- und Sodafabrik, M. G. Levi and F. Ageno, and J. Oesch, also obtained it by the electrolysis of soln. of manganous chloride, etc. G. D. van Arsdale and C. G. Maier found that the hydrated dioxide can be deposited from warm acidic soln. containing more than 5 per cent. of manganous sulphate as a dense, black, lustrous film when the current density is 275 amp. per sq. m. The anodic deposit may be obtained with a 100 per cent. efficiency. The efficiency is decreased by acids in cold soln., but with soln. at 65° to 75° the effect is less. Impurities which are reducing agents decrease the current efficiency proportionally with the amount present. The reactions which occur are assumed to be $Mn^{..} + 2\oplus = Mn^{....}$; followed by hydrolysis, $Mn^{....} + 3H_2O = H_2MnO_3 + 4H^.$; and in acidic soln. this product is deposited as the hydrated dioxide, but in neutral soln. there is also a deposit of the hemitrioxide : $Mn^{..} + H_2MnO_3 \rightleftharpoons Mn(MnO_3) + 2H^.$. F. Hebler found that the composition of the precipitated manganese hydroxides varies considerably.

The peptization of **colloidal hydrated manganese dioxide,** by dil. alkali-lye, or by washing out the excess of adsorbed salts, was observed by A. Gorgeu, K. C. Sen and N. R. Dhar, and by J. M. van Bemmelen—*vide supra.* L. Swiontkowsky, and G. Bredig and A. Marck obtained a coffee-coloured colloidal soln. by reducing a soln. of potassium permanganate with neutral hydrogen dioxide ; and W. Spring and G. de Boeck obtained similar results during the washing of the precipitate obtained by the action of a hypochlorite on manganous hydroxide, or of sodium thiosulphate on potassium permanganate. During the later stages of the washing, a deep brown colloidal soln. is formed. E. Deiss obtained a fairly stable colloidal soln. by reducing a soln. of potassium permanganate by arsenious

acid. If the liquid be evaporated to dryness over sulphuric acid, the colloidal soln. is re-formed by shaking the dry mass with water. When the soln. is allowed to drop into still water, vortex rings are formed resembling those obtained by J. J. Thomson and H. F. Newall with other liquids. The first vortex ring which is formed breaks up into several small rings, and these in turn break into others. All these rings are connected with each other by thin lines of hydrated dioxide, giving the whole system the appearance of a cluster or festoon of rings. If the colloidal soln. be dropped into a salt soln., the hydrated dioxide is precipitated in the form of miniature rings, and by using a very dil. soln. the system of rings will form before coagulation occurs. E. J. Witzemann prepared the colloidal dioxide by the incomplete reduction of a soln. of potassium permanganate by a soln. of glucose in the presence of a little alkali. The colloid can thus be obtained as a viscous liquid, which soon sets to a stiff jelly. E. J. Cuy prepared the colloidal soln. by adding a drop of conc. aq. ammonia every three minutes to $0.05N$-$KMnO_4$, at 90°, until all the permanganate is reduced. The only impurity is alkali hydroxide, wh'ch has a marked stabilizing influence. B. Sjollema obtained the colloid by treating manganese sulphate or acetate with potassium sodium tartrate, and then with hydrogen dioxide and dil. soda-lye. G. Bredig and A. Marck prepared the colloid by the action of hydrogen dioxide on a neutral soln. of potassium permanganate. The hydrogen dioxide soln. should not contain more than 3 per cent. and the permanganate soln. not more than 16 grms. per litre. The resulting brown soln. is then subjected to dialysis until the electric conductivity reaches a constant value. A. Trillat said that a stable colloidal soln. can be readily obtained by oxidizing a manganous salt in the presence of a protective colloid—e.g. albumin, dextrin, gum arabic, sodium albuminates, or starch. E. Deiss observed that colloidal ferric and aluminium hydroxides act as protective colloids if the amount of manganese in soln. is relatively small. If larger quantities of manganese are present, ferric hydroxide behaves quite differently, in that it favours the precipitation of the dioxide. The hydrosol free from alkali was prepared by S.-S. Joshi and T. S. Narayan, and S. Sarvottam and T. S. Narayan. O. Fisseler added a soln. of manganous sulphate to one of sodium lysalbinate or protalbinate, and then treated the liquid with sodium hypochlorite. The dialyzed liquid can be evaporated on a water-bath at 70°, and finally in vacuo over sulphuric acid. The black, glistening plates form a dark brown colloidal soln. when digested with water. G. Bredig and A. Marck found that colloidal soln. of manganese dioxide exhibit large numbers of ultramicroscopic particles. Coagulation takes place on addition of salts, although potassium permanganate is without effect. Acids also bring about coagulation, but small quantities of alkali hydroxides have apparently no influence on the stability of the soln. The stability is dependent on the conditions of preparation, and increases with the dilution of the hydrosol. In presence of gelatin, flocculation by neutral salts is not brought about so readily. The colloidal particles move toward the anode in an electric field. For its action on hydrogen dioxide, *vide supra*, manganese dioxide. According to A. Steopoe, colloidal soln. of manganese dioxide have been prepared by passing ethylene through potassium permanganate soln., the particular advantage of this method being that the removal of electrolytes is unnecessary, since the oxidation product of the ethylene, viz., glycol, is electro-chemically indifferent, and the potassium hydroxide formed is without influence on the stability of the sol. The sol is more stable in stoppered than in unstoppered vessels owing in the latter case to the action of atm. carbon dioxide. In a series of sols containing from 2·2125 to 0·0470 per cent. of manganese dioxide, those of intermediate conc. showed the maximum stability, the dil. sols being almost as unstable as the conc. ones. After preparation the sols separate into two or three transparent, yellow to brown layers, which on stirring do not re-separate. On long keeping, the layers disappear of their own accord, and they are not formed at all in the presence of protective colloids. The phenomenon is explained by assuming that the separation into layers indicates a separation of particles according to their

size. and that the final homogenization represents the disappearance of the smaller particles to the advantage of the larger. N. R. Dhar discussed the colour of the hydrosols. The coagulation was studied by S. Prakash and N. R. Dhar, and J. Mukherjee and co-workers; and the rhythmic precipitation, by D. N. Ghosh. S. Roy and N. R. Dhar observed that insolation favours the coagulation of the hydrosol.

E. Deiss showed that it is probable that the precipitation of manganese dioxide is always preceded by the temporary formation of a colloidal soln. of the substance, coagulation resulting as a consequence of the presence of electrolytes. The formation of the iridescent flakes of manganese dioxide, which can be frequently observed in the oxidation or reduction of manganese compounds, is also attributable to the transient formation of a colloidal soln. N. R. Dhar and co-workers, S. C. Chatterji, and P. B. Ganguly and N. R. Dhar studied the precipitation of colloidal manganese dioxide by electrolytes in the presence of a protective gelatin; and also the adsorption of ions by the colloid. It was found that an ion with the highest precipitation value for the colloid is most strongly adsorbed by the colloid, and conversely. According to B. Ghosh, the adsorption of cations from salt soln. proceeds in the decreasing order: Ba, Sr, Mg, K, Na, and Li; and of the acids H_3PO_4, H_2SO_4, and HNO_3. The subject was studied by S. Ghosh and N. R. Dhar, M. N. Chakravarti and co-workers, and W. Engelhardt. W. Hümmelchen and H. Kappen found that the decomposition of potassium sulphate in aq. soln. by hydrated manganese dioxide is very rapid, for the amount of sulphuric acid formed in 5 mins. is the same as that formed in 3 hrs.—65 per cent. of the potassium in $0.0025N$-K_2SO_4 was adsorbed, but only 6 per cent. of that from a $0.1N$-soln. S. Liepatoff regarded the adsorption of a base from a salt as a chemical process of distribution of base between the acid of the adsorbent and that remaining in soln. W. Chlopin and A. Balandin studied the adsorption of barium chloride and found the effect to be due partly to the reaction $MnO(OH)_2 + BaCl_2 = BaMnO_3 + 2HCl$ and to the adsorption of one of the resultants of the reaction by the colloid. The adsorption of salt soln. was studied by M. Mehrotra and K. C. Sen; and of arsenic trioxide, by K. C. Sen. P. N. Pavloff showed that in the adsorption of silver from a neutral soln. of silver nitrate by freshly prepared hydrated manganese dioxide, the soln. becomes strongly acid. The adsorption of silver ions is regarded as a chemical process which can be explained by the amphoteric character of manganese dioxide, for in this case it acts as an acid. This subject was studied by H. B. Weiser, F. Häffner, L. S. Levy, and N. Schiloff. According to M. Geloso, in the precipitation of hydrated manganese dioxide from a soln. of manganous sulphate by ammonium persulphate, in the presence of iron, nickel, and copper salts, the metals are adsorbed in accord with $u = kC^{1/n}$—confer 5. 39, 9. With ferric ammonium sulphate soln., the adsorption of iron is a function of the concentration of the ferric soln. For each concentration there is an adsorption pressure corresponding with each temp.; the system is thus univariant and no compounds are formed. As the amount of adsorption increases with rise of temp., the phenomenon is endothermic; moreover, adsorption is correlated with the state of aggregation of the precipitate, as its extent is much decreased by prolonged digestion of the precipitate before adding the ferric soln. The relative amount of precipitant (ammonium persulphate) which conditions the size of the solid particles formed thus has some influence on the adsorption. G. Kreimer observed the preferential adsorption of iron from soln. containing aluminium sulphate; and A. W. Pilkoff, the adsorption of radioactive ionium, and uranium-X. H. Udluft found that dolomite adsorbs ferric hydroxide sol but not manganese dioxide sol, whereas clay adsorbs both. Manganese dioxide and ferric hydroxide sols exert a protective action on one another. Humus, however, precipitates ferric hydroxide but not manganese dioxide. The hydrogen carbonate ion precipitates ferric hydroxide when unprotected, but not manganese dioxide and humus sols. According to B. Sjollema, colloidal manganese dioxide gives characteristic reactions with oxydase reagents, irrespective of whether it has been dialyzed or not. It at

once imparts a blue colour to an alcoholic soln. of guaiacum resin, and to a soln. of
p-phenylenediamine hydrochloride. In the presence of light it oxidizes quinol
rapidly, yielding crystals of quinhydrone. Aniline sulphate is at once coloured
violet or blue. Pyrogallol is oxidized, yielding a dark-coloured precipitate. It acts
as a catalyst, decomposing hydrogen dioxide. It does not oxidize hydriodic acid in
neutral, alkaline, or acidic soln. It does not oxidize tyrosine in acidic or alkaline
soln., in this respect resembling the ordinary oxydases. By agitating samples of
quinol soln. with colloidal manganese dioxide, some in presence of peroxydase from
horse-radish, that is, *Cochlearia armoracia*, and some without it, it can be shown that
the oxidation of the quinol and its transformation into quinhydrone by the man-
ganese dioxide is facilitated by the presence of the peroxydase. In the oxidation of
quinol, a mixture of colloidal manganese dioxide and a peroxydase behaves like the
system peroxydase+oxygenase, so that the manganese plays the part of oxygenase.
The coagulation of the colloidal soln. was discussed by S. Ghosh and N. R. Dhar,
N. G. Chatterji and N. R. Dhar, A. Ivanitzkaja and L. Orlova ; and the mutual
precipitation of manganese dioxide, ferric oxide, alumina, and silica by
W. N. Simakoff. M. A. Iljinsky and co-workers studied the adsorption of manganese
dioxide from solid suspensions in water by wool, cotton, and silk fibres.

The general properties of the hydrated dioxide have been discussed in connection
with the ordinary dioxide. A. Simon and F. Feher doubted if a stable stoichiometric

hydrate of manganese dioxide
exists. This is in agreement with
the fact that water begins to be
evolved at 70°, and there is no evi-
dence of a definite compound on
the vap. press. curves. The results
with two samples are summarized
in Fig. 50. Acetone and alcohol
remove a large proportion of the
water of hydration, leaving MnO_2.
0·45 to 0·50H_2O. The hydrated
dioxide is a black or brownish-black
flocculent powder which, in the
presence of other metal oxides, may

Fig. 50.—Vapour Pressure Curves of Hydrated
        Manganese Dioxides.

have its tint modified. J. M. van Bemmelen obtained a red variety by the hydrolysis
of a soln. of the disulphate. W. Wernicke gave 2·58 for the sp. gr. of the hydrate ;
and for the indices of refraction for the *E*-, *D*-, and *C*-lines, respectively 1·944,
1·862, and 1·801. A. Soos studied the optical properties. P. Hausknecht found
that the magnetic susceptibility is about twice that of anhydrous manganese dioxide.
C. R. A. Wright and A. E. Menke said that when confined over conc. sulphuric
acid, the hydrated dioxide slowly loses water for many months ; and at 100°
water is lost until the composition of the hydrated dioxide is $3MnO_2.H_2O$ or
$4MnO_2.H_2O$, but it cannot be freed from water by heating it to 100°, or even to
210°, at which temp. it begins to give off oxygen. A. Gorgeu gave 400° for its
temp. of decomposition. According to C. Drucker and R. Hüttner, the mono-
hydrate dried at the following temp. contains the proportions of water indicated :

	100°	163°	275°	315°	400°	547°	(700°)
H_2O . .	6·7	4·6	3·3	2·4	1·8	0·9	0·3 per cent.

W. C. Bray and H. D. Draper studied the adsorption isotherms. For the decom-
position of the dioxide with the evolution of oxygen, *vide supra*. H. N. Morse said
that the precipitated hydrated dioxide is stable only in the presence of potassium
permanganate or of manganese hemiheptoxide—otherwise it loses oxygen, forming
a lower oxide. W. Hümmelchen and H. Kappen studied the decomposition of
soln. of neutral salts, whereby an acid is liberated when in the presence of hydrated
manganese dioxide. G. Almkvist found that a litre of water at 20° dissolves

0·43 mgrm. of the hydroxide, $MnO(OH)_2$. E. Ebler and W. Bender found colloidal hydrated manganese dioxide is better than colloidal silica for the adsorption of radium salts from soln. The de-sorption is effected by dissolving the product in hydrochloric acid, and passing in hydrogen chloride to precipitate the radium. For the action on hydrogen dioxide, *vide supra*, manganese dioxide. Hydrated manganese dioxide develops an acidic reaction in contact with neutral salts. The acidic reaction may be conditioned by the relative solubilities of the complex acidic solid and its corresponding salts—as advocated by A. F. Joseph in connection with clays; or the liberation of an acid may be due to an interchange between the cations in soln. and the hydrogen ions of the hydrate, as advocated by J. N. Mukherjee. According to B. Ghosh, there is a parallelism between the effect of neutral salts on the electric charge of hydrated manganese oxides and the conc. of the liberated H·-ions. The capacity of the different cations to liberate H·-ions is in the order $Ba > Sr > Mg > K > Na > Li$, and this order also represents the capacity of these ions to neutralize the negative charge of the surface. The bivalent cations reverse the sign of the charge of the surface, showing that the primarily adsorbed ions are univalent. The electrical adsorption of one bivalent cation will therefore liberate one hydrogen ion. In addition, hydrogen ions are probably replaced by cations penetrating into the mobile sheet of the double layer on account of their osmotic press.

Manganese dioxide is amphoteric, in that it unites with acids to form salts, and with bases to form the so-called permanganites—*vide infra*. There is a group of colloidal hydrated manganese oxide minerals to which F. Klockmann [3] applied the term *manganomelanes*. They were originally amorphous, but some of them afterwards crystallized. The analyses of the various members of the group show great variations, so that specific chemical formulæ have not much support. F. Cornu emphasized the need for separating the colloidal gel forms from the crystalline varieties. This distinction, however, as just indicated, may depend only on whether or not the conditions had been favourable for crystallization after the mineral was formed. The great tendency of the hydrated manganese oxides to adsorb various oxides was emphasized by F. Cornu and co-workers. This explains many of the variations in the analytical data, and how the members of virtually the same mineral species have received different names. F. Cornu and H. Leitmeier traced the hydration sequence in the group : Wad→psilomelane→heptonematite→ pyrolusite.

The *derb Brunsten* of J. G. Wallerius was called *magnesia indurata* by A. Cronstedt, and *schwarz Braunsteinerz* by A. G. Werner, and others. It occurs in bluish-, brownish-, or greyish-black masses which may be botryoidal, reniform, or stalactitic. W. Haidinger called the mineral **psilomelane**—from ψιλός, smooth or naked, and μέλας, black, Analyses were reported by J. F. Bahr, P. Berthier, A. P. Bolley, V. C. Butureanu, H. Copaux, J. W. Döbereiner, G. Dupouy, J. J. Ebelmen, S. F. Emmons, L. L. Fermor, F. Field, W. E. Ford and W. M. Bradley, A. Frenzel, J. N. von Fuchs, L. Gmelin, A. Gorgeu, M. F. Heddle, F. Katzer, H. F. Keller, C. M. Kersten, M. H. Klaproth, F. von Kobell, F. Kossmat and C. von John, N. Kurnakoff and N. Podkopajeff, W. A. Lampadius, A. Lacroix, G. Langhans, C. von Leonhard, K. List, T. Morawsky and J. Stingl, P. Poni, C. F. Rammelsberg, C. Rimatori, L. E. Rivot, M. Savul, E. E. Schmid, A. Schwager and C. W. von Gümbel, H. K. Scott, V. Sevoz and J. Breuilhs, E. Turner, B. Walter, A. Weisbach, and E. T. Wherry, etc. The results show the presence of up to 17 per cent. of BaO, up to 4 per cent. of K_2O, up to 7 per cent. of Fe_2O_3, up to 12 per cent. of water, together with smaller proportions of calcium, strontium, magnesium, aluminium, copper, nickel, lead, zinc, thallium, vanadium, and lithium, as well as antimonates, arsenates, phosphates, chlorides, carbonates, sulphates, silicates, titanates, and sulphides. E. Turner regarded these psilomelanes as mixtures of pyrolusite with $nBaO.Mn_2O_3$, and C. F. Rammelsberg (1841), with $RO.2MnO_2.2H_2O$. K. List gave $2(Mn,R)O.3MnO_2.H_2O$; E. E. Schmid, $8(Mn,R)O.12MnO_2.4H_2O$;

C. F. Rammelsberg (1875), $RO.4MnO_2.1$ to $1\frac{1}{2}H_2O$; and C. F. Rammelsberg (1895), $RO.24MnO_2.4$ to $5H_2O$. H. Laspeyres represented the psilomelanes as derivatives of the acid H_4MnO_5, e.g. $H_2Mn(MnO_5)$. L. L. Fermor regarded them as mixtures of $mR''_2MnO_5.nR'''_4(MnO_5)_3$, where R is mainly manganese. P. Groth regarded the psilomelanes as mixtures of manganous permanganite with a part of the bivalent manganese replaced by Ba, Ca, Mg, Co, Cu, and alkalies. Hence, these are the so-called *baryta-psilomelanes*, *lime-psilomelanes*, *alkali-psilomelanes*, *iron-psilomelanes*, *lithia-psilomelanes*, *copper-psilomelanes*, and *cobalt-psilomelanes*. F. Cornu regarded them as colloidal manganese dioxide with variable quantities of adsorbed manganous and other oxides, etc., of other elements. S. R. B. Cooke and co-workers discussed the identification of psilomelane and manganite. A. E. Reuss, and J. R. Blum found pseudomorphs after calcite, rhodochrosite, fluorite, barytes, and pharmacosiderite. Crystalline varieties of psilomelane were described by J. J. Ebelmen, C. F. Rammelsberg, E. E. Schmid, A. Gorgeu, H. Laspeyres, and A. Lacroix, and they include the varieties romanechite, calvonigrite, leptonematite, and rancieite. J. Orcel and S. Pavlovitch discussed the optical properties of psilomelane. The sp. gr. ranges from 3·3 to 4·7, and the hardness from 5 to 7. F. Beijerinck said that the mineral is a conductor of electricity, and F. Braun, and H. Meyer, that it is a unipolar conductor; but O. Weigel found that if adsorbed water be removed from the pores, the dried mineral shows no unipolar conductivity. E. T. Wherry said that it is a poor radiodetector; W. Ogawa also studied the mineral from this point of view, and he found that there is a thermoelectric current of 79000μ volt with psilomelane and copper, and that the current flows from the mineral to the copper at the hot junction. R. Ambronn gave 268×10^{-6} for the coeff. of magnetization; and the subject was studied by G. Grenet. R. D. Harvey discussed the electrical conductivity of psilomelane; and H. A. J. Wilkens and H. B. C. Nitze, the magnetic separation of the mineral. C. W. Davis studied the solvent action of sulphurous acid. K. Thaddéeff found that boiling sulphuric acid colours the mineral violet; and H. C. Bolton, that with boiling citric acid, carbon dioxide is given off. The mineral also gives other reactions characteristic of hydrated manganese dioxide.

Varieties of psilomelane which have received special names are the barytiferous alkali psilomelane named by A. Lacroix *ebelmenite*—named after J. J. Ebelmen; *lithion-psilomelane*, or the *lithiophorite* of A. Frenzel, from Salm Chateau, Belgium, described by H. Laspeyres; the *skemmatite*—after σκέμμα, a question—from Iva, S. Carolina, described by W. E. Ford and W. M. Bradley; *calvonigrite*, from Kalteborn, near Eiserfeld, with a composition between H_4MnO_5 and H_8MnO_6, and sp. gr. 4·361, described by H. Laspeyres; *rancieite*—not *rancierite*—from Rancié in Ariège, France, so named by A. Lacroix. It is a lime-psilomelane with a sp. gr. between 3·0 and 3·2. It was the *chaux de manganèse argentin* of J. B. L. Romé de l'Isle, and the *manganèse oxyde argentin* of R. J. Haüy. A. Lacroix named the psilomelane from Romanèche, *romanechite*. Its sp. gr. is 4·55, and its composition approximates $H_2(Mn,Ba)Mn_3O_8$. The *leptonematite* or *pesillite* of A. Breithaupt, and M. Adam, regarded as varieties of braunite, may be psilomelanes. The *beldongrite* is a variety found by L. L. Fermor at Beldongri, Central Provinces, India. Its sp. gr. is 3·22. The *lithiophorite* of C. Winkler, F. von Kobell, A. Frenzel, and A. Weisbach is a psilomelane with lithia and alumina. The sp. gr. is 3·1 to 3·6. A. Breithaupt called the lithiophorite from Rengersdorf, *kakochlor*. It has a composition approximating $AlMn_3O_7.4H_2O$. The copper-psilomelane *lampadite* was described by W. A. Lampadius, and A. Frenzel, and represented by C. F. Rammelsberg by $2(MnO.CuO).2MnO_2.3H_2O$, or $mCuO.nMnO_2.aq.$, and by H. Laspeyres by $H_4RMn(Mn_4O_7)$. Its sp. gr. is 3·0 to 3·2. The *pelokonite* of C. F. Richter, and C. M. Kersten, having a sp. gr. 2·5 to 2·7, and *lepidophœite* of A. Weisbach, having a sp. gr. 2·89 to 3·04, are related to lampadite. A cobalt-psilomelane was named *asbolite*—from ασβόλη, soot—by A. Breithaupt. C. F. Rammelsberg represented it by the formula $(CoO)(CuO).2MnO_2.4H_2O$, and H. Laspeyres by $H_8RMn(MnO_9)$. It was analyzed by M. H. Klaproth, J. W. Döbereiner, C. F. Rammelsberg, N. Kurnakoff and N. Podkopajeff, H. Copaux, and A. Lacroix. Its sp. gr. is 2·1 to 2·2. Asbolite appears to be the *cobaltum nigrum* of G. Agricola, the *cobalt terrea fuliginea* of J. G. Wallerius, the *ochra cobalt nigra* of A. Cronstedt, and the *aithalite* of M. Adam. The iron-psilomelane obtained by P. Poni from Brosteni, Roumania, was called *brostenite*. Analyses were reported by V. C. Butureanu, M. Savul, B. Walter, and F. Kossmat and C. von John; they vary from $RO.2$ to $5MnO_2.1$ to $3H_2O$. The sp. gr. is 3·104 to 3·61.

W. V. Smitheringale discussed the X-radiogram, and the action of various etching liquids ; and G. A. Thiel, and S. R. B. Cooke and co-workers observed the action of various reagents on psilomelane, and wad—sulphuric and hydrochloric acids, hydrogen dioxide, and soln. of ferrous and stannous chlorides.

The mineral called **wad** is a soft, black, earthy or compact mineral which may also occur in amorphous, reniform masses, and also as an incrustation and as stains. A branching form is called *dendrite*. It consists of various manganese oxides with cobalt, copper, iron, baryta, alumina, silica, and up to over 20 per cent. of water. A variety of wad is called *bog manganese*. Wad is the *magnesia friabilis terriformis* of A. Cronstedt[4] ; the *earthy ochre of manganese* of R. Kirwan ; the *manganschaum* of D. L. G. Karsten ; and the *groroilite* of P. Berthier. The Derbyshire wad is sometimes pseudomorphous with barytes, and that of Leadhills, with *calcite*. The "wad" of the Cumberland miners is graphite. J. J. N. Huot's *oustite* is the French spelling of wad. Analyses were reported by M. H. Klaproth, E. Turner, L. C. Beck, C. F. Rammelsberg, M. Scheffler, L. J. Igelström, A. S. Woodward, A. Liversidge, M. Weibull, C. Rimatori, B. Bertolio, H. Ludwig, J. Redtenbacher, J. H. L. Vogt, E. Dittler, A. Gorgeu, V. C. Butureanu, C. P. Williams, E. H. S. Bailey, L. L. Fermor, and S. Popoff. A. Lacroix said that wad cannot be regarded as a definite chemical compound ; C. F. Rammelsberg also added : *Alle sonstigen Untersuchungen von Wad lehren dass es Gemenge sind.* That from Upton Pine, Devonshire, can be represented by $MnO.9MnO_2.6H_2O$. The sp. gr. of wad is 2·3 to 3·7. K. Thaddéeff said that some samples are strongly coloured by sulphuric acid, others are feebly coloured, and yet others not at all coloured.

There are some varieties which have received special names : The *wackenrodite* of M. Adam was analyzed by H. W. F. Wackenroder ; it came from Schapbach, Baden, and C. Rimatori described a similar mineral from Bosa and Montresta, Sardinia. The *césarolite* from Tunis, analyzed by H. Buttgenbach and C. Gillet, approximates $H_2PbMn_3O_8$. Its sp. gr. is 5·29. K. Reissacher described a mineral from Wildbad, Gastein, Austria ; it was called *reissacherite*, and contained 27·27 per cent. of water. According to H. Mache, a radioactive substance producing an emanation obtained from the gases and water is found in the reissacherite of the deposits from the thermal springs of Gastein. This mineral, which has a radioactivity approximately equal to that of uranyl nitrate, contains manganese dioxide, ferric oxide, calcium carbonate, barium, and strontium, but neither sulphuric acid nor uranium ; on separation, the radioactive substance is obtained along with the barium and is presumably radium. F. von Kobell described *rabdionite* obtained from the Urals ; its composition approximates $(Cu,Mn,Co)O.(Fe,Mn)_2O_3.2H_2O$, and its sp. gr. is 2·80. G. de Geer, and T. Fegraeus described the *manganese ochre* from Aas, Upsala. It approximates $Mn_3O_4.4H_2O$. K. Nenadkewitsch obtained *zinkdibraunite* from the zinc mines of Olkusz. Its composition approximates $ZnO.2MnO_2.2H_2O$. A. Brunlechner described *zinkmanganerz* from Bleiberg, Carinthia.

A group of oxides intermediate between the monoxide and dioxide has been reported. The members of the group are usually regarded as *manganous manganites* of the type $MnO.nMnO_2$. In order to keep the nomenclature more or less consistent, they are here called **permanganites.** V. H. Veley[5] said that if the hydrated higher oxides are heated in dry nitrogen at 60° to 200°, they are simply dehydrated, and the product readily absorbs oxygen. He thus prepared $Mn_{24}O_{32}.3H_2O$; $Mn_{24}O_{44}.2(4, 6, or 8)H_2O$; $Mn_{24}O_{45}.8H_2O$; $Mn_{24}O_{46}.2(or 3)H_2O$; and $Mn_{24}O_{47}.2H_2O$. A. Gorgeu prepared some by the action of a manganous salt on the so-called alkali or calcium manganites ; A. Guyard, by the action of manganous salts on potassium manganate or permanganate—the products ranged between $3MnO.2MnO_2$ and $MnO.5MnO_2$; and S. U. Pickering, by diluting with water a soln. of hydrated manganese dioxide in hydrochloric acid—the products ranged between $5MnO.16MnO_2$ and $5MnO.36MnO_2$, and appeared to be intermediate stages in the oxidation of manganous oxide to hydrated manganese dioxide (*q.v.*).

B. Franke reported $2MnO.3MnO_2$ to be formed by treating potassium manganic sulphate, $5K_2SO_4.2Mn_2(SO_4)_3$, with water acidulated with sulphuric acid, and washing the product successively with water, alcohol, and ether. The small, dark brown plates form

manganous sulphate and hydrated manganese dioxide when they are allowed to stand in the mother-liquor. W. Reissig reported $MnO.2MnO_2$ to be formed when manganous carbonate is heated in air to 300°. A. Carnot represented the product of the action of hydrogen dioxide on a manganous salt by $MnO.5MnO_2$; A. Gorgeu obtained rather less peroxidic oxygen; while R. Haas said that hydrogen dioxide with manganous hydroxide gives products ranging from Mn_2O_3 to Mn_5O_8. A. Gorgeu obtained the 1 : 5 oxide by the action of chlorine on water with manganous carbonate in suspension; J. Post obtained a product with more dioxide, and A. Gorgeu observed that in the extreme case, with a prolonged action, hydrated manganese dioxide is formed. V. H. Veley obtained $MnO.5MnO_2.3\frac{1}{2}H_2O$, by the action of chlorine on manganous acetate soln. at 52°, when the washed product was dried at 30°–40° in air; when dried at 60°–100°, $MnO.5MnO_2.2H_2O$ was formed; when dried at 160°–170°, $MnO.11MnO_2.1\frac{1}{2}H_2O$; and at 200°–250°, $MnO.11MnO_2.H_2O$. If heated in oxygen, that gas is absorbed at 100°, while at 180°–190° $MnO.23MnO_2.2H_2O$ is formed, and at a red-heat Mn_2O_3 is produced. C. Lepierre obtained $MnO.5MnO_2$ as a brown, crystalline powder of sp. gr. 3·41, by melting manganese sulphate for some hours with potassium nitrate. W. Spring and M. Lucion, A. Carnot, and G. C. Stone obtained $MnO.10MnO_2$, by treating a manganous salt with nitric acid—with or without potassium chlorate; and O. T. Christensen obtained $MnO.22MnO_2.28H_2O$ by boiling a soln. of ammonium manganate with nitric acid.

A. Guyard suggested that the reaction between a manganous salt and potassium permanganate can be represented $3MnO.A+K_2O.Mn_2O_7=K_2O.A+2A+3MnO+Mn_2O_7$, where A stands for the acid anhydride. He supposed that the $3MnO.Mn_2O_7$ then changed to manganese dioxide: $3MnO.Mn_2O_7=5MnO_2$, and suggested that the following *manganous manganates*, $3MnO.MnO_3$, $4MnO.MnO_3$, and $5MnO.MnO_3$ exist, as well as the *manganous permanganates*, $3MnO.Mn_2O_7$, $4MnO.Mn_2O_7$, and $5MnO.Mn_2O_7$.

§ 12. The Permanganites

The chromites are salts of the acid anhydride Cr_2O_3, and the ferrites of the acid anhydride Fe_2O_3, so that here the salts of the acid anhydride Mn_2O_3 are called manganites ; hence, the salts of the acid anhydride MnO_2 are called **permanganites,** those of the acid anhydride MnO_3, manganates, and those of the acid anhydride Mn_2O_7, permanganates. A. Gorgeu[1] regarded hydrated manganese dioxide as *acide manganeux*, manganous acid, H_2MnO_3, so that manganese dioxide becomes manganous anhydride, MnO_2, and the salts $RO.nMnO_2$, permanganites. The acidic properties of hydrated manganese dioxide are very feeble, and as a result show a great tendency to form polymerides—**polypermanganites.** A. S. Cocosinschy represented the formation of the polypermanganites by :

$$O=Mn\begin{array}{c} OH \\ OH \end{array} \quad O=Mn\begin{array}{c} OH \\ O:H \end{array}$$

$$O=Mn\begin{array}{c} OH \\ O H \\ OH \end{array} = H_2Mn_2O_5 \qquad O=Mn\begin{array}{c} OH \\ OH \end{array} = H_2Mn_3O_7 \quad . . \qquad H_2Mn_nO_{2n+1}$$

$$O=Mn\begin{array}{c} OH \\ OH \end{array} \qquad O=Mn\begin{array}{c} OH \\ OH \end{array}$$

C. R. A. Wright and A. E. Menke doubted the existence of potassium permanganites as chemical individuals, since the product obtained by reducing permanganate with glycerol—*vide infra*—does not have the composition $K_2O.8MnO_2$. $3H_2O$ assigned to it by T. Morawsky and J. Stingl, for, neglecting the water of hydration, it varied considerably in composition—*e.g.* $K_2O.3MnO.9MnO_2$; $2K_2O$. $13MnO.22MnO_2$; and $3K_2O.2MnO.18MnO_2$. It was also found that the product of the reduction of permanganate by sulphur dioxide in the cold approximated $K_2O.2MnO.12MnO_2$. L. Swiontkowsky, and C. Weltzien also observed that the products of the reduction of permanganate by hydrogen dioxide are very variable in composition. A. Gorgeu, and J. Post found that the oxidation of manganous hydroxide by air in the presence of a soln. of potassium hydroxide approximates $K_2O.25MnO.27MnO_2.nH_2O$, which is not far from $Mn_2O_3.H_2O$. J. M. van

Bemmelen explained the variation in composition of the different alkali manganites reported by different investigators by assuming that they are mixtures of the products of the hydrolysis of one or more permanganites, while the permanganites prepared by wet processes are adsorption products of hydrated manganese dioxide with bases. A similar view was taken by E. Deiss.

On the other hand, W. Biltz showed that hydrated manganese dioxide, $MnO_2.H_2O$, has acidic qualities, and he called it *manganige Säure*—our permanganous acid, H_2MnO_3. This hydrate was obtained by treating hydrated manganese dioxide with ammonia, cooled by a freezing mixture of solid carbon dioxide, and pumping off the ammonia. The residue corresponds with $MnO_2.H_2O$. If the pressure, p mm., be measured during the extraction of ammonia, and the corresponding mol. ratio $NH_3 : MnO_2$ determined, the results, when plotted, furnish the curve, Fig. 51. There are breaks corresponding with $H_2O.NH_3.MnO_2$ and $H_2O.2NH_3$.

FIG. 51.—The Vapour Pressure of the Ammonium Permanganites.

MnO_2. The former, $H_2O.NH_3.MnO_2$, is taken to be the acidic salt, **ammonium hydropermanganite**, $(NH_4)HMnO_3$; and the other, $H_2O.2NH_3.MnO_2$, the normal salt, **ammonium permanganite**, $(NH_4)_2MnO_3$.

G. Rousseau melted a mixture of 3 grms. of sodium hydroxide and 1·5 grms. of manganous chloride, and then added 3 grms. of sodium nitrate, and raised the temp. to dull redness. The mixture was then kept for 4 hrs. in a covered crucible at the volatilization temp. of sodium hydroxide. At an orange-red heat **sodium pentapermanganite**, $Na_2O.5MnO_2$, is formed, and at a white-heat small, black, glistening needles of **sodium dodecapermanganite**, $Na_2O.12MnO_2$, appear. The crystals are washed with boiling water. The pentapermanganite is also formed in black, octahedral plates by adding 10 grms. of sodium chloride to the mixture used in the previous preparation, heating it until the sodium chloride is volatilized, and washing the cold product with water. If sodium permanganate be heated to 300°, and the cold mass extracted with water, there remain black microscopic crystals of **sodium octopermanganite**, $Na_2O.8MnO_2.5H_2O$. The crystals lose 4 mols. of water at 150°–180°, and all the water is lost at 250°; no other change occurs at 440°. This compound is also formed by melting a mixture of sodium manganate and chloride at 500° and washing the product with boiling water; at 800° the *tetrahydrated dodecapermanganite*, $Na_2O.12MnO_2.4H_2O$, is formed; at 1000°, **sodium hexadecapermanganite**, $Na_2O.16MnO_2.8H_2O$; at 1200°–1300°, the octopermanganite is again formed; and at a white-heat, the hydrated dodecapermanganite. P. Schottländer prepared a complex *sodium glycerylpermanganite*, $Na_2[Mn(C_3H_5O_3)_2]$, by treating manganese dioxide with glycerol and soda-lye. For A. S. Cocosinschy's observations on the action of heat on the sodium salt, *vide infra*.

According to C. F. Rammelsberg, **potassium dipermanganite**, $K_2O.2MnO_2$, is prepared by strongly heating potassium permanganate; when this is extracted with water, it is resolved into **potassium pentapermanganite**, $K_2O.5MnO_2$, thus: $5K_2Mn_2O_5=2K_2Mn_5O_{11}+3K_2O$. A. S. Cocosinschy found that the proportion of potassium in the washed product decreases with the temp. of calcination of the potassium permanganate, and similarly with the sodium salt:

	600°	700°	800°	900°	1000°	1100°
K content .	29·21	28·09	26·28	23·79	22·82	18·57 per cent.
Na content .	31·01	30·70	29·12	28·65	26·71	24·29 per cent.

A. Gorgeu found that when carbon dioxide is passed into a soln of potassium manganate, a soln. of permanganate and a yellow precipitate, $K_2O.5MnO_2.nH_2O$, are formed. The formula just indicated represents the composition of the washed product. There is probably some hydrolysis, because if washed with water con-

taining 0·3 per cent. potassium hydroxide, the product is **potassium tetraper-manganite,** $K_2O.4MnO_2.nH_2O$; and if with water containing 1 per cent. potassium hydroxide, there remains **potassium tripermanganite,** $K_2O.3MnO_2.nH_2O$. If a soln. of potassium permanganate be decomposed by a soln. of potassium hydroxide or carbonate, a precipitate approximating $K_2O.5MnO_2.nH_2O$ is formed, and when the liquid is boiled, this product passes into soln. as potassium manganate. J. Post made some observations on this subject. If the precipitate be washed with hot water, C. R. A. Wright and A. E. Menke found that its composition corresponds with $4K_2O.21MnO_2.19H_2O$; while, according to T. Morawsky and J. Stingl, if the precipitate be washed with hot water and dried at 100°, it forms **potassium octoper-manganite,** $K_2O.8MnO_2.3H_2O$. According to P. Solstein, the permanganite $K_2O.8MnO_2.3H_2O$, or $KH_3Mn_4O_{10}$, is formed by the action of iodine on a soln. of potassium permanganate ; M. Gläser obtained a similar product by using thio-sulphate in place of iodine, but M. Hönig and E. Zatzek said that the precipitate produced by thiosulphate in alkaline soln. has the composition $K_2O.6MnO_2.3H_2O$, or $KH_3Mn_3O_8$. T. Morawsky and J. Stingl obtained $K_2O.8MnO_2.3H_2O$ by reducing a neutral soln. of potassium permanganate by alcohol, glycerol, potassium thio-cyanate, or potassium oxalate. G. Rousseau melted a mixture of 3 grms. of potassium carbonate and 5 grms. of potassium chloride, and added, in small quantities at a time, 3 grms. of potassium manganate. If heated for 8 hrs. at a high temp., and the cold mass extracted with water, there remains trihydrated potassium octopermanganite, in black plates which lose their water at 150° to 160°. If the operation be conducted at a lower temp., black plates of **potassium hexa-decapermanganite,** $K_2O.16MnO_2.6H_2O$, are formed. They lose their water at 130°–200°, and dissolve freely in conc. hydrochloric acid. If a mixture of 10 grms. of potassium chloride and 3 grms. of potassium manganate be heated until the alkali chloride is volatilized, and the cold product washed with boiling water, black plates of **potassium dotricontapermanganite,** $K_2O.32MnO_2.10H_2O$, are formed.

J. Volhard obtained an impure copper permanganite by the action of a copper salt on a warm soln. of potassium permanganate ; and in the reaction $2KMnO_4+3MnSO_4+7H_2O \rightleftharpoons 2KHSO_4+H_2SO_4+5H_2MnO_3$, studied by A. Guyard, and J. Volhard, if other metal salts be present, the corresponding permanganite may be formed—e.g. with zinc sulphate : $4KMnO_4+5ZnSO_4+6MnSO_4+14H_2O=4KHSO_4+7H_2SO_4+5(HO.MnO.OZnO.MnO.OH)$. The brownish-black **copper hemiennea-permanganite** prepared by P. B. Sarkar and N. R. Dhar by adding potassium permanganate to a mixed soln. of copper and manganous sulphates and boiling has the composition $2CuO.9MnO_2.14H_2O$. A. F. Jolles also prepared copper per-manganite in a similar way. According to M. Salinger, when a mixture of manganous and copper sulphates is treated with ammonium persulphate, a copper permanganite is precipitated ; and if the mixed soln. is treated with hydrogen dioxide, the precipitate has the composition of a **copper manganous permanganite,** $4CuO.MnO.7MnO_2.8H_2O$. The *lepidophœite* of A. Weisbach may be (MnO,CuO). $5MnO_2.9H_2O$----vide supra. A. Gorgeu obtained **copper tetrapermanganite,** $CuO.4MnO_2$, by the repeated action of a dil. soln. of a cupric salt on moist hydrated manganese dioxide ; it decomposes into the hypomanganite at a red-heat. H. Bau-bigny and P. Rivals obtained the impure *hydrate*, $CuO.4MnO_2.H_2O$, by evaporating a soln. of potassium bromide, copper sulphate, and potassium permanganate to dry-ness. The action is incomplete. A. Gorgeu found that if a cold, sat. soln. of silver permanganate is treated with hydrogen dioxide, a brown precipitate of **silver per-manganite,** $Ag_2O.MnO_2$, is formed ; while if potassium octopermanganite is treated with silver nitrate, **silver octopermanganite,** $Ag_2O.8MnO_2.3H_2O$, is formed ; while M. Salinger obtained **silver decapermanganite,** $Ag_2O.10MnO_2.3H_2O$, by treating a mixture of manganous and silver nitrates with ammonium persulphate. By proceeding as in the case of the copper salt, but using soln. of silver nitrate and manganous sulphate, P. B. Sarkar and N. R. Dhar obtained deep black **silver heptapermanganite,** $Ag_2O.7MnO_2.9H_2O$; and by using a soln. of gold chloride,

below 0·1 per cent. conc., they obtained a reddish-brown **gold permanganite** which contained only a small proportion of gold. The silver permanganites were also studied by M. N. Chakravarti and N. R. Dhar, and S. C. Chatterji and N. R. Dhar.

H. St. C. Deville observed the formation of a calcium permanganite in the reduction of manganese (*q.v.*) in a lime crucible. By adding a large excess of bleaching powder to a soln. of manganous chloride, so that the liquid remains alkaline, J. Pattinson, and A. Gorgeu obtained a black calcium permanganite, approximating $CaO.MnO_2$; J. Volhard also obtained permanganites of the alkaline earths by adding their salts to a hot soln. of potassium permanganate. In W. Weldon's process for chlorine (*q.v.*) the by-product of manganous chloride is treated at 55° with an excess of calcium hydroxide and a blast of air, when a black, impure calcium permanganite is precipitated : $MnCl_2+2Ca(OH)_2+O=CaO.MnO_2+CaCl_2+2H_2O$. Other products are also formed, *e.g.* $CaO.2MnO_2$ and $MnO.MnO_2$. The subject was discussed by A. Lamy, G. Lemoine, E. Mylius, J. R. Wagner and W. Schenk, W. Odling, G. Lunge, G. Lunge and B. Zahorsky, J. Wiernik, E. Kopp, C. Jezler, F. Kuhlmann, J. Post, etc. According to E. Dufau, **calcium tritapermanganite,** $3CaO.MnO_2$, is obtained by heating manganese or manganese oxide in a lime crucible in an electric arc furnace for a few minutes. The crystalline mass is not altered when heated in oxygen ; it is decomposed by cold water, and an aq. soln. of sugar dissolves both calcium and manganese oxides, to form a dark reddish-brown soln., which is decolorized by acids, and from which alcohol separates a rose-coloured precipitate. At a red-heat the compound is attacked with incandescence by chlorine and bromine to form calcium chloride or bromide respectively ; iodine acts less energetically ; hydrogen chloride attacks it below redness ; hydrochloric acid dissolves it with the evolution of chlorine ; molten potassium chlorate is without action ; cold nitric acid has very little action, but the hot acid dissolves it with the evolution of gas ; and molten potassium nitrate is without action. G. Rousseau prepared brownish-red crystals of **calcium hemipermanganite,** $2CaO.MnO_2$, by heating for an hour a mixture of calcium oxide and chloride and manganous chloride ; and black prismatic crystals of **calcium permanganite,** $CaO.MnO_2$, by heating for a couple of hours a mixture of 15 grms. of calcium chloride and 3 or 4 grms. of calcium carbonate, adding 2 grms. of manganous chloride, and extracting the cold mass with water. It is soluble in fuming hydrochloric acid and insoluble in water. If the mixture be heated for half an hour, **calcium dipermanganite,** $CaO.2MnO_2$, is formed ; and if heated for 6 hrs., black needles of **calcium tripermanganite,** $CaO.3MnO_2$, are formed. G. Rousseau represented these compounds by the graphic formulæ :

$$Ca\diagdown^{O}_{O}\diagup Mn\diagdown^{O}_{O}\diagup Ca \qquad O{=}Mn\diagdown^{O}_{O}\diagup Ca \qquad \begin{matrix} O\diagdown\\ O\diagup\end{matrix}Mn{-}O\diagdown Ca \atop \begin{matrix}O\diagdown\\ O\diagup\end{matrix}Mn{-}O\diagup \qquad O{=}Mn\diagdown^{O}_{O}\diagup^{Mn-O}_{Mn-O}\diagdown^{Ca}$$
According to J. Risler, **calcium pentapermanganite,** $CaO.5MnO_2$, is formed when a mixture of potassium permanganate and calcium chloride is heated to redness and the potassium chloride extracted by boiling water from the cold product. The black crystalline mass is freely soluble in hydrochloric acid, and less soluble in nitric acid. P. B. Sarkar and N. R. Dhar added potassium permanganate to a mixed soln. of manganous and calcium chlorides and boiled the liquid. Reddish-brown **calcium heptapermanganite,** $CaO.7MnO_2.11$ to $14H_2O$, was precipitated. G. Rousseau prepared **strontium permanganite,** $SrO.MnO_2$, by heating for a few hours a molten mixture of 15 grms. of strontium chloride, 2 grms. of strontia, and a gram of manganous chloride ; if the temp. is between 1000° and 1100°, **strontium dipermanganite,** $SrO.2MnO_2$, is produced in black needles in about 8–10 hrs. J. Risler obtained a black, crystalline powder of **strontium pentapermanganite,** $SrO.5MnO_2$, by the process used for the corresponding calcium salt. P. B. Sarkar and N. R. Dhar obtained reddish-brown **strontium heptapermanganite,** $SrO.7MnO_2$.

11H$_2$O, by the process used for the calcium salt.   P. Schottländer prepared *strontium diglycerylpermanganite*, Sr[Mn(C$_3$H$_5$O$_3$)$_2$], by a process analogous to that used for the sodium salt.   G. Rousseau prepared **barium permanganite,** BaO.MnO$_2$, in black plates or needles, by heating a mixture of 10 grms. of manganous chloride and 2 grms. of barium permanganate for about 4 hrs. at 1500°–1600°, or by similarly heating a mixture of 3 grms. of baryta and a gram of manganous chloride with an excess of barium bromide.   The soluble salts are washed from the product with boiling water, and finally with acidulated water.   The sp. gr. is 5·85 ; and the compound is freely soluble in hydrochloric acid with the evolution of chlorine ; it is sparingly soluble in nitric acid.   T. Morawsky and J. Stingl prepared the *hydrate*, BaO.MnO$_2$.H$_2$O, by the action of hydrogen dioxide on barium permanganate. D. Balareff gave 240° for the reaction temp. of barium oxide and manganese dioxide. G. Rousseau obtained **barium dipermanganite,** BaO.2MnO$_2$, in black plates, by heating a mixture of 3 grms. of baryta, a gram of manganous chloride, and an excess of barium bromide to 1000° ; and also by heating barium permanganate for 15 hrs. at 320° in the absence of air.   J. Risler obtained a dark olive-green, crystalline powder of **barium pentapermanganite,** BaO.5MnO$_2$, as in the case of the corresponding calcium salt.   G. Rousseau reported **barium heptapermanganite,** BaO.7MnO$_2$, to be formed by heating barium permanganate, in the absence of air, for many hours at 320°.   The powdered product is mixed with acidulated water, and finally washed with boiling water.   P. B. Sarkar and N. R. Dhar obtained black BaO.7MnO$_2$.7H$_2$O, as in the case of the calcium salt.   T. Morawsky and J. Stingl obtained **barium octopermanganite,** BaO.8MnO$_2$.3H$_2$O, by treating the corresponding potassium salt with barium chloride.

According to P. de Wilde and A. Reychler, if a mixture of magnesium sulphate and manganous chloride be heated in air at a red-heat, **magnesium manganous dipermanganite,** 3MgO.MnO.2MnO$_2$, is formed.   A. Gorgeu obtained **magnesium tetrapermanganite,** MgO.4MnO$_2$, by repeatedly digesting freshly-precipitated, hydrated manganese dioxide in a neutral soln. of a magnesium salt.   E.. Dufau obtained **magnesium permanganite** as a reddish-brown powder by heating a mixture of magnesium oxide and manganese dioxide for a few minutes in an electric arc furnace.   The hard, black, crystalline mass furnishes a reddish-brown powder, which is not very stable.   It is slowly decomposed by cold water, and a soln. of sugar dissolves both manganese and magnesium ; it is freely soluble in acids, evolving chlorine with hydrochloric acid, and a gas is given off with nitric acid. If a soln. of manganous chloride be treated with an excess of magnesium hydroxide, and a blast of air be passed through the mixture, magnesium permanganite is formed, as in the case of W. Weldon's process for calcium permanganite (*q.v.*). E. Bückse represented the reaction MnCl$_2$+MgCl$_2$+2H$_2$O+O=MgO.MnO$_2$+4HCl. W. Weldon also heated in air a mixture of manganese and magnesium chlorides and obtained chlorine and a permanganite : 2MgCl$_2$+MnCl$_2$+2O$_2$=3Cl$_2$+2(MgO.MnO$_2$). J. Volhard also obtained a magnesium permanganite by treating a warm soln. of potassium permanganate with a magnesium salt.   P. B. Sarkar and N. R. Dhar obtained black **magnesium hemiheptapermanganite,** 2MgO.7MnO$_2$.13H$_2$O, by proceeding as in the case of the copper salt.   A. F. Jolles obtained barium permanganite in a similar way.   J. Risler prepared **zinc pentapermanganite,** ZnO.5MnO$_2$, by the method used for the calcium salt.   J. Volhard obtained a **zinc permanganite** by the action of a zinc salt on a warm soln. of potassium permanganate.   M. Salinger prepared **zinc tritapermanganite,** 3ZnO.MnO$_2$.7$\frac{1}{2}$H$_2$O, by treating a mixed soln. of manganous and zinc sulphates with ammonium persulphate ; if a soln. of alkali manganate and zinc sulphate be employed, the precipitate contains a higher proportion of zinc.   A. Gorgeu obtained **zinc tripermanganite,** ZnO.3MnO$_2$, and **cadmium pentapermanganite,** CdO.5MnO$_2$, by digesting freshly-precipitated hydrated manganese dioxide in a neutral aq. soln. of a zinc or cadmium salt.   P. B. Sarkar and N. R. Dhar obtained brownish-yellow **cadmium tridecapermanganite,** CdO.13MnO$_2$. 21H$_2$O, by proceeding as in the case of the copper salt.   A. F. Jolles prepared

cadmium permanganite in a similar way. A. Gorgeu reported **mercury octopermanganite,** $HgO.8MnO_2.3H_2O$, to be formed by the action of a mercuric salt on a soln. of the corresponding potassium salt. P. B. Sarkar and N. R. Dhar obtained deep black **mercuric henapermanganite,** $HgO.11MnO_2.6H_2O$, by proceeding as in the case of the copper salt.

M. Salinger did not prepare **aluminium permanganite** by adding ammonium persulphate to a soln. of ammonium aluminium sulphate and ammonium manganese sulphate ; a negative result was also obtained by the use of ammonium chromium sulphate, but J. A. Krenner, and J. Loczka described a *manganospinel,* $(Mn,Mg)(Al,Mn)_2O_4$, obtained in the slags of a blast furnace at Menyhaza, Hungary. P. B. Sarkar and N. R. Dhar obtained reddish-brown aluminium permanganite by boiling a soln. of manganous sulphate and potash-alum mixed with potassium permanganate. They also obtained a brownish-grey **thallic permanganite,** $6Tl_2O_3.5MnO_2.7H_2O$, from soln. of thallous and manganous sulphates boiled with potassium permanganate.

P. B. Sarkar and N. R. Dhar prepared grey **stannous permanganite,** $2SnO.5MnO_2.2H_2O$, from a mixed soln. of stannous chloride and manganous sulphate, boiled with potassium permanganate. A. F. Jolles obtained insoluble **lead permanganite,** $PbO.MnO_2$, by boiling lead permanganate with a reducing liquid. It is not decomposed by neutral or alkaline soln., but if heated in air or steam, it forms lead manganate. J. Orcel and S. Pavlovitch discussed the optical properties of these minerals. P. B. Sarkar and N. R. Dhar obtained black **lead tetrapermanganite,** $PbO.4MnO_2.8H_2O$, when a mixed soln. of lead nitrate and manganous sulphate is treated with potassium permanganate. A. F. Jolles obtained lead permanganite in a similar way. J. Risler obtained **lead pentapermanganite,** $PbO.5MnO_2$, by the method used for the calcium salt. W. Lindgren and W. F. Hillebrand found a fibrous mineral of a brownish-black colour at Coronadogang, Arizona, and they called it **coronadite.** The analysis corresponds with **lead tripermanganite,** RMn_3O_7, or $R''_4H_2Mn_{12}O_{29}$. It may be regarded as a derivative of orthomanganous acid, $3H_4MnO_4 = H_2Mn_3O_7 + 5H_2O$. E. E. Fairbanks found that it consists of hollandite and another lead mineral. L. L. Fermor found that his observations agreed with the formula $R''MnO_5$, where R denotes Pb and Mn. The sp. gr. is 5·246, and the hardness 4. H. Buttgenbach and C. Gillet described a related steel-grey mineral from Sidi-Amor-ben-Salem, Tunis ; they called it **césarolite**—after G. Cèsaro. In the idealized state it corresponds with PbO, 44·46 per cent. ; MnO_2, 51·95 ; H_2O, 3·59. Its sp. gr. is 5·29. Nitric acid extracts only about 3·35 per cent. of the manganese, and its formula approximates $PbO.3MnO_2.H_2O$, making it a salt of the acid $H_4Mn_3O_8$, analogous to the **romanechite** of A. Lacroix—named from its occurrence at Romanèche—and represented by $H_2(Mn,Ba)Mn_3O_8$—*vide supra,* psilomelane. F. Zambonini and V. Caglioti found that romanechite corresponds with $H_2(Mn,Ba)Mn_4O_{10}$. There is also the Indian mineral **hollandite,** described by L. L. Fermor. It occurs in tetragonal bipyramids with $a : c = 1 : 0.2039$, and of a silver-grey or black colour. Its sp. gr. is 4·70 to 4·95, and its hardness 6. The analyses approximate $mR''_2MnO_5.nR'''_4(MnO_5)_3$, where R'' is mainly H_2, K_2, Mn, or Ba ; and R''', Fe, Mn. L. L. Fermor represented the relations between these minerals of what he called the hollandite group :

Hollandite group					
Pb very low	H$_2$O high, Fe low	.	.	ROMANECHITE
Ba low or high	H$_2$O low, Fe high	.	.	HOLLANDITE
Pb high : Ba very low	.	.	.	.	CORONADITE

E. E. Fairbanks found that, like coronadite, romanechite consists of hollandite and a lead mineral.

P. B. Sarkar and N. R. Dhar obtained deep black **bismuth manganite,** $Bi_2O_3.7MnO_2.10H_2O$, from a nitric acid soln. of bismuth nitrate, and manganous sulphate treated with potassium permanganate ; and brownish-red **vanadium permanganite,** $V_2O_5.5MnO_2.10H_2O$, by using ammonium metavanadate in place of

the bismuth salt.   M. Gröger prepared hydrated **chromium permanganite**, $Cr_2O_3.3MnO_2.nH_2O$, or $Cr_2(MnO_3)_3.nH_2O$, by allowing mixed soln. of manganous chloride and sodium chromate to stand a short time.   The dark brown precipitate is formed in accord with $3MnCrO_4 = CrO_3 + Cr_2(MnO_3)_3$.   It forms chromic acid when treated with sulphuric acid.   For the work of H. Struve, E. Péchard, C. Friedheim and O. Allemann, C. Friedheim and M. Samelson, A. Rosenheim, and A. Rosenheim and H. Itzig on the complex **molybdenum permanganites,** *vide* manganese molybdates, **10.** 60, 11 ; and for A. Just's, and A. Roger and E. F. Smith's observations on **tungsten permanganites,** *vide* manganese tungstates, **10.** 61, 12.   P. B. Sarkar and N. R. Dhar obtained reddish-brown **uranyl manganite** by the general process indicated above.

For the **manganese permanganites,** *vide supra*, manganese dioxide.   S. L. Penfield and H. W. Foote obtained a black mineral, crystallizing in cubes with octahedral cleavage, from Simpson, Utah ; it was called **bixbyite**—after M. Bixby.   The analysis was thought to correspond with **ferrous permanganite,** $FeO.MnO_2$, and the constitution to be $Fe(MnO_3)$.   W. Zachariasen, and L. Pauling and M. D. Shappell found that the X-radiograms agreed with a space-lattice isomorphous with manganese hemitrioxide, $(Fe,Mn)_2O_3$—*vide* ferric oxide.   The sp. gr. is 4·945, and the hardness, 6 to 6·5.   The *brostenite*, from Brosteni, Roumania, was regarded by P. Poni as an iron manganese permanganite, $(Fe,Mn)O.2MnO_2.2H_2O$, but V. C. Butureanu, and H. Corti observed that the mineral is not uniform, or homogeneous.   M. Salinger obtained **ferric permanganite,** $3Fe_2O_3.10MnO_2.3H_2O$, by adding ammonium persulphate to a soln. of ammonium ferric sulphate and ammonium manganese sulphate.   A. Gorgeu obtained **ferric dodecamanganite,** $Fe_2O_3.12MnO_2$, by digesting freshly-precipitated hydrated manganese dioxide with a hot, aq. soln. of a ferric salt.   The mineral **sitaparite** from Sitapar, Central Provinces, India, was described by L. L. Fermor as a dark bronze-green, crystalline mass, with a composition approximating $CaO.9Mn_2O_3.4Fe_2O_3.MnO_2$, or **calcium manganic ferric permanganite.**   Its sp. gr. is 4·93 to 5·09, and its hardness is 7.   M. Salinger prepared **cobalt permanganite,** $CoO.MnO_2.2H_2O$, as a brown precipitate from a soln. of cobalt sulphate and potassium permanganate ; and A. Gorgeu obtained **cobalt hexapermanganite,** $CoO.6MnO_2$, by igniting the product obtained by digesting freshly-precipitated hydrated manganese dioxide in aq. soln. of a neutral cobalt salt ; and **nickel pentapermanganite,** $NiO.5MnO_2$, was obtained in a similar way. P. B. Sarkar and N. R. Dhar treated nickel sulphate by the general process, and obtained brownish-black **nickel hexapermanganite,** $NiO.6MnO_2.11H_2O$; and they also prepared a reddish-brown **platinum permanganite,** which, like the gold salt, contained only a small proportion of basic oxide.

§ 13. Manganese Trioxide and the Manganates

In 1659, J. R. Glauber [1] melted magnesia (*i.e.* pyrolusite) with fixed alkali, and obtained a mass which when dissolved in water produced a most delicate purple-coloured liquid which slowly changed its colour to blue, red, and green. The anonymous *Schlüssel zu dem Cabinet der geheimen Schatzkammer des Natur*, attributed to J. Waiz, said that when Piedmont magnesia (pyrolusite) is fused with saltpetre and the mass treated with water, a green soln. is obtained, which becomes blue, violet, and finally rose-red. Here the colours are said to appear in the reverse order to that reported by J. R. Glauber. J. H. Pott made a similar observation to that reported by J. Waiz, who was right, for C. W. Scheele observed that when manganese dioxide is fused with potassium nitrate, an intense green mass is produced, which he regarded as a salt of a manganiferous acid. It was also observed that the mass forms a green soln. with water, which when much diluted, or when allowed to stand for some time, acquires a red colour. Accordingly, C. W. Scheele named this salt *mineralisches Chamäleon*. A. F. de Fourcroy made a superficial attempt to find the composition of mineral chamaleon, and C. F. Bucholz regarded the red soln. as being formed by the oxidation of the green soln. by atmospheric oxygen. M. E. Chevreul showed that the alkali nitrate can be replaced by non-oxidizing alkali hydroxide or carbonate, as in J. R. Glauber's experiment, but P. F. Chevillot and W. F. Edwards found that the oxygen necessary for the production of the green salt is absorbed from the air. G. Forchhammer, H. Aschoff, A. Béchamp, N. Beketoff, and E. Mitscherlich then showed that the green salt, soluble in water, is the potassium salt of a dibasic acid, *manganic acid*, H_2MnO_4, where the manganese is sexavalent, and that the salt is a *manganate*, K_2MnO_4. H. Aschoff, and E. Mitscherlich also showed that the violet salt is not an acid salt of manganic acid, but represents a more highly oxidized monobasic acid, *permanganic acid*, $HMnO_4$, where the manganese is septavalent, and the salt is a *permanganate*, $KMnO_4$.

According to B. Franke,[2] when the green soln. obtained by dissolving potassium permanganate in sulphuric acid is exposed to direct sunlight in the presence of moist

air, the manganese heptoxide—*vide infra*—which is formed separates and then decomposes into manganese dioxide, **manganese trioxide,** MnO_3, and a blue gas giving certain reactions of ozone, but differing from that substance in being decomposed at 150°, and in being soluble in conc. sulphuric acid. He obtained the blue gas by the action of moist air on the sulphuric acid soln. of potassium permanganate, and regarded it as **manganese tetroxide,** MnO_4, which he supposed was formed in accord with $(MnO_3)_2SO_4 + H_2O = MnO_4 + MnO_3 + H_2SO_4$. It is said that the blue gas is best made by passing a current of carbon dioxide, sat. with moisture, on to the surface of the olive-green liquid, and leading the escaping gas through two U-tubes, one of which is empty and the other filled with calcium chloride. The manganese trioxide collects in the first tube, while the second retains the tetroxide. The tetroxide is said to be more volatile than the trioxide, to be more blue in colour, to be less readily attacked by water, and to be decomposed by the action of sulphuric acid and ether. T. E. Thorpe and F. J. Hambly were unable to obtain the slightest indication of the blue, gaseous tetroxide under these conditions.

According to B. Franke, manganese trioxide is formed as a dark red mass when the green soln. of manganese oxysulphate is distilled in the presence of water. It is best prepared by dropping 20 c.c. of the green soln. obtained by dissolving 5 to 8 grms. of potassium manganate in 100 c.c. of conc. sulphuric acid into a small bulb containing 10 grms. of dehydrated sodium carbonate : $(MnO_3)_2SO_4 + Na_2CO_3 = Na_2SO_4 + CO_2 + O + 2MnO_3$. The red fumes are passed into a U-tube surrounded by a freezing mixture, in which they condense to a dark red, amorphous mass. T. E. Thorpe and F. J. Hambly recommended filling the U-tube with fragments of broken glass, to prevent the pink fumes being carried along with the escaping carbon dioxide. The freezing mixture of ice and salt is necessary to retard the decomposition of the condensed product, since at ordinary temp. it gradually loses oxygen and is converted into manganese dioxide. The curious behaviour of the pink fume led them to conclude that it was really an extremely finely-divided solid. It floats in the air like a cloud of sal-ammoniac or sulphur trioxide, and like these substances may, if suspended in a sufficiently large volume of air or carbon dioxide, be passed through water practically unabsorbed. The trioxide is red in thin layers, and dull dark red, almost black, in thick layers. B. Franke said that the trioxide has a peculiar odour, and volatilizes at about 50° as a violet vapour, with partial decomposition into crystalline manganese dioxide and oxygen ; this decomposition is complete when the substance is heated. It is sparingly soluble in water ; a litre of water containing 50 mgrms. of the substance has an intense red colour. When the vapour is passed into aq. soda or potash, alkaline manganates are produced. The reaction employed for detecting small quantities of manganese by means of potassium chlorate depends on the formation of the trioxide. According to T. E. Thorpe and F. J. Hambly, when manganese trioxide is absorbed by dil. sulphuric acid, a clear pink or reddish-pink soln. is obtained, in which the manganese and oxygen are in the ratio of 1 to 3. There is no evidence to show that this soln. contains free manganic acid. If the substance were decomposed as in the aq. soln., the ratio of O to Mn would be as 1 to 3, provided that all the manganese were retained in soln. When manganese trioxide is dissolved in conc. sulphuric acid, it forms a soln. of the same colour as that obtained on dissolving potassium permanganate in oil of vitriol. This may be regarded as additional evidence for the existence of $(MnO_3)_2SO_4$. The substance is soluble in caustic potash, and gives a green soln. similar to that of potassium manganate. Manganese trioxide gives the reactions for ozone : it affects mercury and liberates iodine from potassium iodide. It blackens silver, but the stain can be shown to be due to manganese dioxide. B. Franke said that when manganese trioxide is passed into water, the manganic acid, H_2MnO_4, which is formed is very unstable and decomposes into manganese dioxide, oxygen, and a dark red soln. of permanganic acid. T. E. Thorpe and F. J. Hambly represented the reaction : $3MnO_3 + H_2O = 2HMnO_4 + MnO_2$. Analyses by B. Franke, and by T. E. Thorpe and F. J. Hambly agree with the formula MnO_3.

F. R. Lankshear found that the dark red, amorphous solid supposed to be manganese trioxide has a m.p. —6°, and its analysis corresponds with a ratio of permanganate to manganese dioxide of 4·8 : 1. It is inferred that the alleged manganese trioxide gas is nothing more than an impure permanganic acid. According to S. R. Scholes, the violet tint of manganese glass is due to compounds of manganic oxides, because the pink soln. obtained by extracting the glass with hydrofluoric and 30 per cent. sulphuric acids gives a light brown precipitate when diluted with water.

E. Mitscherlich [3] prepared **potassium manganate,** K_2MnO_4, by heating a mixture of any oxide of manganese with potassium hydroxide, carbonate and nitrate, or a mixture of potassium hydroxide and chlorate. In the one case, with the hydroxide or carbonate, the oxygen is derived from atm. air, and in the other case, from the nitrate or chlorate. The green soln. obtained by dissolving the cold cake in water is filtered and evaporated in vacuo over sulphuric acid. Green crystals of potassium manganate are formed. A similar process was used by P. F. Chevillot and W. F. Edwards, H. McCormack, A. Béchamp, N. Beketoff, R. W. Stimson, and C. Zwenger. According to P. F. Chevillot and W. F. Edwards, a mixture of 44 parts of manganese dioxide with four times its weight of potassium hydroxide absorbs 9·4 to 10·4 parts of oxygen when it is heated in oxygen gas. A. Béchamp found that the absorption of oxygen begins at a dull red-heat. and then proceeds rapidly until completed. According to E. Mitscherlich, if manganese dioxide is heated with the alkali hydroxide or carbonate in a closed vessel, the oxygen required for the formation of the manganate is derived from the manganese dioxide : $3MnO_2$ $=Mn_2O_3+MnO_3$. N. Beketoff observed that the splitting of manganese dioxide into oxide and acid, in the presence of potassium hydroxide, begins at 130°, and the absorption of oxygen proceeds at a higher temp. The lower manganese oxides begin to take up oxygen at a dull red-heat to form the manganate. P. F. Chevillot and W. F. Edwards said that if a mixture of alkali hydroxide and manganese dioxide is heated in nitrogen, no manganate is produced, but C. W. Eliot and F. H. Storer showed that the potassium manganate is formed at about 180° in nitrogen, and at a red-heat it oxidizes some nitrogen to nitrogen oxide. According to P. F. Chevillot and W. F. Edwards, and P. Thénard, potassium permanganate at 240° is reduced to manganate. A. F. Jolles obtained potassium manganate by heating eq. amounts of potassium permanganate and potassium hydroxide at a dull red-heat ; G. Kassner and H. Keller said that the manganate is not formed if eq. quantities are used : it is necessary to have 1·5 to 2·0 times more potassium hydroxide. The permanganate should be dissolved in the alkali-lye and the soln. stirred while the water is evaporated, and then the mixture heated to 200° or 300°. According to R. Luboldt, P. Thénard, and H. Aschoff, if an alkaline soln. of permanganate be treated with a feeble reducing agent, or if it is boiled with potash-lye of sp. gr. 1·33, or heated to 130°, a dark green soln. of the manganate is formed and the soln. becomes green. Oxygen is given off when the permanganate is heated with the alkali-lye.

According to P. Askenasy and S. Klonowsky, the potassium manganate of the highest degree of oxidation which can be prepared by the oxidation of an excess of the lower oxides of manganese in the presence of potassium hydroxide, in an atm. containing oxygen, contains a small excess of the alkali. The results obtained by starting with manganese dioxide or with manganese hemitrioxide are almost the same. In both cases the quantity of manganate formed increases as the temp. rises up to the point at which the press. of the oxygen is equal to the dissociation press. of the manganate ; at higher temp. the manganate is, of course, decomposed. In air the best temp. is about 600° ; in oxygen it is near 700°. Using an excess of manganese oxide, some 60 to 65 per cent. of the potassium hydroxide employed is converted into manganate under the best conditions. Prolonging the time of heating beyond one hour does not materially increase the yield. The absorption of oxygen takes place at 240°, but more slowly than at higher temp. According to H. I. Schlesinger and co-workers, when finely-powdered manganese dioxide is heated with potassium hydroxide in a current of air, complete oxidation is frequently

attained only by re-moistening and re-heating the mixture. The yield of potassium manganate varies with the proportion of potassium hydroxide present; at about 300° practically all the manganese dioxide is converted into manganate when two mols. of potassium hydroxide are used for each mol. of manganese dioxide. Mangani-manganates are not formed under these conditions, but larger amounts of potassium hydroxide cause the manganate to decompose into mangani-manganate. The yield of manganate is lowered when sodium hydroxide is used in place of potassium hydroxide. O. Sackur fused in a current of air manganese dioxide with an excess of alkali carbonate sufficient to hold the manganese compound in soln., and so permit of full oxidation. The absorption of oxygen by the fused mass ceases as soon as the at. proportion of available oxygen to manganese is 1·6. This value is independent of the conc. of the manganese in the fused mass, and of the press. of the oxygen above the fusion. Consequently, there is no state of equilibrium between the different stages of the oxidation of manganese in the fusion and the oxygen in the gaseous phase, but a definite compound is formed with $Mn : O = 1 : 2·6$, or Mn_5O_{13}—that is, $2MnO_2.3MnO_3$. The fused cake is dark green, and with a little water, or alkaline soln., it forms a dark green soln. of manganate and a dark brown precipitate of manganese dioxide; while with much water, or dil. acids, it forms a violet soln. of permanganate and manganese dioxide. A similar result was obtained when the potassium carbonate was replaced by potassium hydroxide, but with sodium carbonate the atomic proportion of available oxygen to manganese was 1·5 instead of 1·6. A mixture of potassium and sodium carbonates in equal proportions gave the same proportions as with sodium carbonate alone. The fusions containing sodium salts were grass-green in colour, as opposed to the dark green of the potassium compound. Calcium oxide gave similar results to sodium carbonate. When oxygen is absorbed by the fusion, carbon dioxide is simultaneously evolved, as shown by the equation : $5MnO_2 + \frac{3}{2}O_2 + nK_2CO_3 = Mn_5O_{13}, nK_2O + nCO_2$. Unless oxygen is passed for a considerable time after the evolution of carbon dioxide has ceased, the compound formed in the fusion is $5M_2O.Mn_5O_{12}$, when M is either K or Na. When oxidation is complete, the ratio of the lowering of the m.p. of alkali carbonate to the concentration of the manganese in gram-atoms per 1000 grms. of fusion is constant, and equal to 43 with potassium carbonate and 35 with sodium carbonate. Hence, the solute in each case contains one gram-atom of manganese per mol, so that their formulæ are $K_2MnO_{3·6}$ and $Na_2MnO_{3·5}$, respectively. There is no very definite relation between the oxygen absorbed and the carbon dioxide evolved, but the results agree with the assumption that $8K_2O.Mn_5O_{13}$ is formed, in accord with $5Mn_2O_3 + 10K_2CO_3 + 11O = 10CO_2 + 2(5K_2O.Mn_5O_{13})$, and $2(5K_2O.Mn_5O_{13}) + 6K_2CO_3 = 6CO_2 + 2(8K_2O.Mn_5O_{13})$. At 900° to 950° manganic oxide and potassium carbonate interact in an atm. of nitrogen in accord with $19Mn_2O_3 + 5K_2CO_3 = 5K_2O.Mn_5O_{13} + 11Mn_3O_4 + 5CO_2$. The compound $8K_2O.Mn_5O_{13}$ may be regarded as an additive compound of quadri- and sexivalent manganese, namely, potassium manganitomanganate, $2(K_2O.MnO_2).3(2K_2O.MnO_3)$. With sodium carbonate in place of potassium carbonate, sodium manganitomanganate, $4Na_2O.Mn_2O_5$, or $(2Na_2O.MnO_2)(2Na_2O.MnO_3)$, is formed, with the permanganite $2Na_2O.MnO_2$ as an intermediate product. F. Bahr and O. Sackur measured the dissociation press. of fused mixtures of manganese dioxide and potassium hydroxide, and obtained the isothermal dissociation curve, Fig. 40, at 661°, for potassium permanganate. The results show that the final product of dissociation is potassium permanganite, K_2MnO_3, which has no dissociation press., even at 1000°. In potassium manganate the atomic proportion of available oxygen to manganese is $1 : 1·6$, corresponding with the composition $3K_2MnO_4.2K_2MnO_3$. The formation of products further saturated than this is attributed to supersaturation. This degree of oxygen corresponds with the compound $Mn_5O_{13}.8K_2O$. V. Auger confirmed the existence of $5K_2O.Mn_5O_{13}$ and $2Na_2O.Mn_2O_5$, and he isolated the sodium salt by heating in a silver crucible 10 grms. of potassium permanganate with 100 grms. of sodium hydroxide and 20 c.c. of

water. The crystalline mass was washed with a conc. soln. of sodium hydroxide, when the compound was obtained as a micro-crystalline, bluish-green powder, which underwent immediate decomposition on treatment with water. For O. Dieffenbach's electrolytic process, *vide infra*, potassium permanganate.

E. Mitscherlich's analysis agreed with the formula K_2MnO_4; and R. T. Colgate regarded the substance as having the constitution:

$$K\ K$$
$$KO.O.Mn.O.\overset{.}{O}.\overset{.}{O}.O.Mn.O.OK$$
$$KO.O.Mn.\overset{.}{O}.\overset{.}{O}.\overset{.}{O}.\overset{.}{O}.Mn.O.OK$$
$$\overset{.}{K}\ \overset{.}{K}$$
H. Lessheim and co-workers discussed the constitution of the manganates. E. Mitscherlich said that potassium manganate furnishes green crystals; C. Zwenger, that the crystals have a brownish-red tinge, and are not green; while H. Aschoff added that the smallest crystals are so nearly black as to appear to be opaque. E. Mitscherlich found the axial ratios of the rhombic crystals to be $a:b:c$ $=0.5638:1:0.7570$; and added that the crystals are isomorphous with those of potassium sulphate, selenate, and chromate. The subject was discussed by J. W. Retgers; and the effect of manganates on the crystallization of sodium chlorate, by H. E. Buckley. F. Bahr and O. Sackur found that when potassium manganate is heated, it dissociates into potassium permanganite and oxygen, a reaction which has the following dissociation pressures, p mm. of mercury:

	507°	516°	543°	572°	610°	629°	653°	667°
p	11	15·1	27·3	52·6	138·5	221	381·5	532

P. Askenasy and S. Klonowsky obtained rather higher results, namely, 40 mm. at 548°, and 763 mm. at 661°, Fig. 52. If the oxygen is pumped off, the dissociation press. remains constant until about two-thirds of the oxygen given by the equation $K_2MnO_4=K_2MnO_3+\frac{1}{2}O_2$ has been expelled. Afterwards the press. of the oxygen falls. This is taken to show that solid soln. are formed as indicated above. E. Franke gave for the conductivity, λ, of soln. of an eq. of manganic acid in v litres of water at 25°:

v	64	128	256	512	1024
λ	345·2	346·6	346·1	343·9	342·8

The acid was here obviously unstable and decomposing. According to O. Sackur and W. Taegener, and O. Sackur, the normal potential for the electrochemical change permanganate to manganate: $MnO_4'=MnO_4''$ $+F$ is $E_H=0.61$ volt, when deduced from the e.m.f. of the cell $Pt:KMnO_4,K_2MnO_4,KOH:0.8N\text{-}KOH,HgO:$ Hg, at room temp. This value is independent of the acidity or alkalinity of the soln.; but it changes with the conc. of manganate and permanganate in accord with $E_H=0.61+0.058\{\log[MnO_4']-0.058\log[MnO_4'']\}$ volt. The normal potential of the electrochemical change $MnO_4''+2H_2O=MnO_2+4OH'+2F$ is nearly $E_H=0.50$ volt for normal soln. of alkali hydroxide. This value is calculated from measurements of the e.m.f. of a cell of the type $(Pt):K_2MnO_4,KOH:$ $0.8N\text{-}KOH,HgO:Hg.$ Since with a high concentration of alkali-lye, the separation of manganese dioxide may be attended with the evolution of oxygen, a film of manganese dioxide is deposited on the platinum. The variation in the potential with changes in the concentrations of potassium manganate and alkali hydroxide is represented by $E_H=0.50+0.029\{\log[MnO_4'']-0.116\log[OH']\}$ volt. The oxidation potential also increases very much with a decrease in the alkalinity of the soln. For a neutral molar soln. of MnO_4'', $E_H=1.31$ volts, and for a normal soln., $E_H=2.12$
FIG. 52.—Isothermal Dissociation Curve of Potassium Manganate.

volts. The soln. are not stable, and the potential for change into MnO_2 exceeds that for the change into permanganate, so that one-third of the manganate changes to manganese dioxide : $MnO_4'' + 4H^· = MnO_2 + 2H_2O + 2F$, for which $E_H = 2.12$ volts, and two-thirds to permanganate : $2MnO_4'' + 2F = 2MnO_4'$, for which $E_H = 0.61$ volt. The free energy of this transformation with normal concentrations is $2F(2.12 - 0.61)$ volt, or $3.02F$ joules, or 69.6 Cals. The free energy changes with variations in the concentration of the acid, permanganate, and manganate in accord with $Q = 69,600 + 5320 \log [H^·] + 0.3990 \log [MnO_4''] - 2660 \log [MnO_4']$ cals. The tendency of the manganate to change into permanganate thus increases markedly with an increase in the acidity of the soln. The change can occur even in feebly alkaline soln. O. Sackur and W. Taegener also calculated that for N-KOH soln. the dissociation press. for the change $2K_2MnO_4 + 2H_2O \rightleftharpoons 2MnO_2 + 4KOH + O_2$ is nearly 10^6 atm. C. E. Ruby gave for the molar electrode potentials at 25°, with solid manganese dioxide : $MnO_2 + 4OH' + 2\oplus = MnO_4'' + 2H_2O$, -0.664 volt ; $MnO_2 + 4OH' + 3\oplus = MnO_4' + 2H_2O$, -0.647 volt ; and $MnO_2 + 2H_2O + 3\oplus = MnO_4' + 4H^·$, -1.757 volts. C. E. Ruby also found the equilibrium constant $K = [MnO_4']^2[OH']^4/[MnO_4'']^3$ for the reaction $3K_2MnO_4 + 2H_2O = MnO_{2\,solid} + 2KMnO_4 + 4KOH$ to be 53 at 45°. The corresponding decrease of free energy is 10,500 joules, and the e.m.f. of a cell in which it occurs is 0.054 volt. H. I. Schlesinger and H. B. Siems found the equilibrium constant for the reaction between manganate and permanganate ions $K = [MnO_4']^2[OH']^4/[MnO_4'']^3$ to be $K = 16$ at 25°.

The manganates are usually supposed to contain sexivalent manganese, like the isomorphous sulphates and selenates. C. F. Schönbein regarded them as complex salts of manganese dioxide and a dioxide of an electropositive metal—e.g. Na_2O_2, K_2O_2, BaO_2, etc. P. F. Chevillot and W. F. Edwards observed that potassium manganate forms a green soln. with **water,** but the colour rapidly changes through blue, violet, and purple to carmine-red, in proportion as the excess of potassium hydroxide is removed from the salt by water—especially if the water is hot, or if a large proportion is present. E. Mitscherlich said that the salt is decomposed by water, yielding a red soln. of the permanganate and a deposit of hydrated manganese dioxide : $3K_2MnO_4 + 2H_2O = 2KMnO_4 + 4KOH + MnO_2$. C. Fromherz added that a soln. of the salt in air-free water kept in air-tight bottles, completely filled, turns red. This shows that the affinity of water for the alkali is sufficient to decompose the salt. G. Forchhammer, and C. Fromherz noted the precipitation of hydrated manganese dioxide when the green soln. of manganate passes into a red soln. of the permanganate. The reaction was studied by H. Aschoff, and E. Mulder added that on account of the formation of potassium hydroxide, the conversion of manganate to permanganate is not complete. E. Mitscherlich observed that potassium manganate dissolves without decomposition in an aq. soln. of **potassium hydroxide,** forming a green soln., from which the salt can be separated by evaporation in vacuo. The salt so obtained is contaminated with alkali hydroxide. If the soln. in alkali-lye be exposed to air, the hydroxide is converted into carbonate, and the green manganate then changes to red permanganate and hydrated manganese dioxide. J. W. Retgers represented the reaction with a soln. of alkali hydroxide : $15K_2MnO_4 + 9H_2O = 10KMnO_4 + K_2O.5MnO_2 + 18KOH$—vide supra for the observations of P. Askenasy and S. Klonowsky, and O. Sackur. Owing to the instability of soln. of potassium manganate in water, the solubility of the salt in water cannot be satisfactorily determined ; but being stable in alkaline soln., solubility measurements for different concentrations of potassium hydroxide were made by O. Sackur and W. Taegener. The following is a selection from their results, expressed in S mols of K_2MnO_4 per litre of the alkaline soln. :

		0°	10°	20°	30°	40°	50°	60°	70°	80°
	2N-KOH	0.907	1.013	—	1.252	—	—	—	—	—
	4N-KOH	0.554	—	—	0.772	0.852	0.938	1.003	1.074	1.143

This shows that the solubility of the salt in dil. alkali-lye is very great; it increases only a little with a rise of temp., and it decreases markedly with increasing concentration of the lye. According to C. M. Tessié du Motay, the salt is decomposed when heated in water vapour: $2K_2MnO_4+2H_2O=4KOH+Mn_2O_3+3O$, and the reaction has been utilized for the preparation of oxygen by H. Vogel, H. Weppen, M. Dutremblay and M. Lugan, R. D. Bowman, J. H. Parkinson, A. F. S. Bellone, G. Webb and G. H. Rayner, F. Fanta, and C. M. Tessié du Motay and C. R. M. de Maréchal. The original manganate is regenerated by heating the mixture in air. E. Mitscherlich, and P. F. Chevillot and W. F. Edwards noticed that the presence of **acids**—carbonic acid from the air, sulphuric acid, nitric acid, or other non-reducing acid—accelerates the passage of the manganate to permanganate in soln., and G. Forchhammer observed that the change is always accompanied by the deposition of hydrated manganese dioxide. H. Aschoff represented the reaction: $3K_2MnO_4+2CO_2=2KMnO_4+MnO_2+2K_2CO_3$. This is not in agreement with T. L. Phipson's assumption that the transformation is simply an effect of the withdrawal of alkali from the permanganate. E. Mitscherlich briefly mentioned a **potassium dihydrotetramanganate,** $3K_2MnO_4.H_2MnO_4$, which he considered to be isomorphous with the salt $3K_2SO_4.H_2SO_4$.

G. Städeler found that **chlorine** transforms alkali manganate into permanganate: $2K_2MnO_4+Cl_2=2KCl+2KMnO_4$. Chlorine is evolved when a manganate is treated with conc. **hydrochloric acid,** and, according to J. W. Retgers, some manganese trichloride (q.v.) is formed. J. B. Senderens observed that when the alkali manganate soln. is boiled with **sulphur** a thiosulphate is formed, and the reaction can be represented: $2K_2MnO_4 + 5S + 2H_2O = Mn_2O_3.H_2O + 2K_2S_2O_3 + H_2S$. C. F. Schönbein found that a soln. of a manganate is reduced and decolorized by **hydrogen sulphide,** forming manganous sulphide and sulphur; and similarly with **sulphur dioxide.** H. Aschoff found that conc. **sulphuric acid** forms anhydrous manganese heptoxide and dioxide. E. Mitscherlich added that when a soln. of potassium manganate is boiled with sulphuric acid—*vide supra*—hydrated manganese dioxide is precipitated and oxygen is evolved; L. Kahlenberg and W. J. Trautmann observed no reaction when a mixture of powdered **silicon** and the manganate is heated over a bunsen burner, but a reaction occurs at a higher temp. The manganates detonate on red-hot **carbon.** P. F. Chevillot and W. F. Edwards noted that the presence of **ammonium carbonate** in soln. favours the transformation of manganate to permanganate; and J. W. Retgers, L. Santi, and G. Doyer van Cleef represented the reaction with **ammonium salts** in the presence of ammonia by the equation: $3K_2MnO_4+4NH_4Cl=2KMnO_4+MnO_2+4KCl+4NH_3+2H_2O$. E. Mitscherlich observed that the manganate soln. behaves with boiling **nitric acid** as it does with sulphuric acid: $K_2MnO_4+2HNO_3=2KNO_3+MnO_2+H_2O+O$. As indicated above, **carbon dioxide** in soln. favours the transformation of manganate to permanganate. W. Müller found that when the salt is heated to redness in the vapour of **carbon disulphide,** the reaction can be represented: $K_2MnO_4+2CS_2=K_2S_3+MnS+2CO_2$. J. Holluta studied the action of manganates on **formic acid,** and on **formaldehyde.** A. F. Jolles found that a soln. of the manganate furnishes insoluble compounds with some of the **metal oxides,** e.g. cobalt oxide. According to A. Gawalowsky, the addition of a soln. of **ferric chloride** to a soln. of a manganate furnishes oxygen and a soln. of the so-called *liquor ferri oxychlorati*; while with **copper sulphate,** oxygen is developed and a whitish-grey precipitate, which is oxidized by nitric acid to copper sulphate, is formed. J. W. Retgers found that **thallous salts** are oxidized to thallic salts by potassium manganate. J. W. Retgers prepared mixed crystals of potassium manganate with **rubidium manganate,** Rb_2MnO_4, or with **cæsium manganate,** Cs_2MnO_4, showing that both salts are isomorphous with potassium manganate. If a neutral soln. of potassium manganate be treated with ammonium sulphate, the green soln. immediately reddens, as indicated above. An alkaline soln. of manganate decomposes the ammonium salt. Hence, **ammonium manganate,** $(NH_4)_2MnO_4$, could not be prepared.

P. F. Chevillot and W. F. Edwards prepared **sodium manganate,** Na_2MnO_4, by heating to redness a mixture of manganese dioxide and sodium hydroxide in air ; J. G. Gentele obtained the manganate by an analogous process at a dull red-heat ; and C. M. Tessié du Motay and C. R. M. de Maréchal worked the process at 400°. E. Bothe heated to redness manganese dioxide with three times its weight of sodium carbonate in a current of air and obtained a 74·6 per cent. yield of sodium manganate. F. Wöhler said that no sodium manganate is formed when a mixture of manganese dioxide and sodium nitrate is heated out of contact with air ; nor did C. M. Bradbury succeed in preparing sodium manganate by this process. V. Auger said that the salt is easily obtained by heating sodium permanganate in a silver or platinum dish with twice the calculated quantity of sodium hydroxide ; oxygen begins to form at 115°, and the reaction is complete at 125°. On cooling, sodium manganate separates in black crystals with a violet reflex. J. W. Retgers said that sodium manganate is probably not isomorphous with sodium sulphate and selenate. W. G. Mixter gave for the heat of formation $(Mn,3O,Na_2O)=169\cdot0$ Cals. ; and $(MnO_2,O,Na_2O)=49\cdot4$ Cals. E. Mitscherlich said that the salt is too soluble to allow it to be purified by crystallization from aq. soln., but J. G. Gentele said that if it be boiled with water, it forms a green soln. which can be filtered through powdered glass, and slowly cooled to 0°, when a pale green mass of radiating crystals of the *decahydrate,* $Na_2MnO_4.10H_2O$, is formed. It is dried on a porous tile. When dissolved in water, the green salt is partially decomposed. R. Funk could not prepare this green hydrate, but he always obtained crystals of sodium carbonate coloured dark green by the mother-liquor. V. Auger, however, found that when an aq. soln. of the salt is cooled by a freezing mixture, the decahydrate appears in black needles of m.p. 17°, and the crystals appear to be isomorphous with those of sodium chromate. A soln. containing an excess of sodium hydroxide deposits black prisms of the *hexahydrate,* $Na_2MnO_4.6H_2O$; and a soln. in 5 per cent. sodium hydroxide soln. deposits black prisms of the *tetrahydrate,* $Na_2MnO_4.4H_2O$, when it is concentrated by evaporation. The salt behaves towards steam as in the case of potassium manganate, and can be used for the preparation of oxygen in a similar way (*q.v.*). J. W. Retgers found that if powdered manganese dioxide be melted at a white-heat with a mixture of lithium carbonate and nitrate, the manganese dioxide does not dissolve as it does in the case of the sodium salts, and consequently he could not prepare **lithium manganate,** Li_2MnO_4—*vide infra.* A. Gawalowsky found that copper sulphate decomposes a soln. of potassium manganate—*vide supra* —and a **copper manganate,** $CuMnO_4$, has not been prepared. A. F. Jolles obtained the basic salt **copper dihydroxymanganate,** $(CuOH)_2MnO_4$, by the action of an excess of ammonia and potassium manganate on a soln. of a copper salt : $2Cu(NH_3OH)_2+K_2MnO_4=4NH_3+2KOH+(CuOH)_2MnO_4$. J. W. Retgers said that **silver manganate,** Ag_2MnO_4, appears *nicht existenzfähig zu sein.* Silver oxide seems to be too feeble a base to unite with manganic acid. A neutral soln. of silver nitrate colours red a green neutral soln. of sodium manganate, and silver permanganate is deposited. A similar reaction occurs when an ammoniacal soln. of silver nitrate and a green ammoniacal soln. of potassium manganate are mixed.

According to P. F. Chevillot and W. F. Edwards, if equal parts by weight of baryta and manganese dioxide be heated to bright redness in air, oxygen is absorbed, and a dark green insoluble mass of **barium manganate,** $BaMnO_4$, is formed. H. Abich used barium carbonate in place of baryta, and employed a higher temp. ; he thus obtained a dark green crystalline mass. G. Forchhammer, and C. Fromherz heated the manganese dioxide with barium nitrate, and washed the product with water ; they thus obtained an insoluble emerald-green powder. J. A. Hedvall and N. von Zweigbergk observed that barium dioxide begins to react at 200° with manganous oxide : $2BaO_2+MnO=BaMnO_4+BaO$; at about 140° with manganosic oxide : $5BaO_2+Mn_3O_4=3BaMnO_4+2BaO$; at 250° with manganic oxide : $3BaO_2+Mn_2O_3$ $=2BaMnO_4+BaO$; and between 350° and 550° with manganese dioxide : $BaO_2+MnO_2=BaMnO_4$. A. Safarik added manganese dioxide to a soln. of barium

hydroxide in molten potassium chlorate, and washed the product with boiling water. E. Fleischer heated a mixture of barium permanganate and barium oxide ; E. Donath, a mixture of manganese dioxide or carbonate with barium dioxide ; and C. Huggenberg, a mixture of manganese dioxide, barium hydroxide. and sodium nitrate. According to W. Lindner, when a soln. of potassium permanganate and barium chloride is boiled, barium manganate is precipitated, and a similar process was used by E. Fleischer, A. F. Jolles, and R. Böttger. C. Fromherz obtained the manganate by treating manganic acid with an excess of baryta-water ; and E. Mitscherlich, and H. Aschoff obtained it by allowing a mixed soln. of barium permanganate and hydroxide to stand for some time. A. Gorgeu obtained barium manganate by reducing a soln. of the permanganate with hydrogen dioxide. G. Kassner and H. Keller found that barium manganate forms a permanganite when treated with hydrogen dioxide, but the manganate is re-formed when the permanganite is calcined in air. According to H. I. Schlesinger and H. B. Siems, barium manganate may be prepared by the cautious addition of a sat. soln. of potassium permanganate to a boiling sat. soln. of barium hydroxide, carbon dioxide being excluded. The bluish-black barium manganate is washed by decantation, separated, dried at 110°, and then in a vacuum desiccator over phosphorus pentoxide. It is decomposed by phosphoric acid : $3BaMnO_4+4H_3PO_4=2Ba(H_2PO_4)_2+Ba(MnO_4)_2+MnO_2+2H_2O$. The solubility product determined from the equilibrium conc. in $BaMnO_4+K_2CO_3\rightleftharpoons BaCO_3+K_2MnO_4$ is $2\cdot6\times10^{-10}$, assuming that under equilibrium conditions potassium carbonate and manganate are equally ionized. E. Wedekind gave $10\cdot1\times10^{-6}$ for the magnetic susceptibility of barium manganate. A. Safarik found the green powder or acicular to tabular crystals of barium manganate to have the sp. gr. 4·85 at 23°. E. Wedekind and C. Horst examined the magnetic susceptibility. Barium manganate is insoluble in water, and decomposed by acids. G. Kassner used barium manganate for bleaching purposes, and re-calcined the resulting barium permanganite to re-form the manganate.

A. Rosenstiehl heated to redness an intimate mixture of manganese dioxide, barium nitrate, and barium hydroxide in the proportions 1 : 4 : 6 to 8, washed the product with boiling water, then with cold water, and obtained an emerald-green powder consisting of $3BaO.2MnO_3$. It is stable when dry, but is decomposed when moist and exposed to air. According to F. Rose, the product has been used as a pigment—*Cassel's green, manganese-green*, and *Rosenstiehl's green*. L. Schad, C. Vogt, and A. Buntrock used china clay or barytes as a component of the mixture used for preparing the pigment, in order to make the mass less fusible during calcination. According to G. Kassner and H. Keller, and A. F. Jolles, when the pigment is prepared in the wet way, its composition is $BaMnO_4$ with less than a mol. of water ; while V. Auger and M. Billy represented it by the formula $Ba_3(MnO_4)_2.H_2O$.

P. F. Chevillot and W. F. Edwards prepared a **strontium manganate** by calcining a mixture of manganese dioxide and strontia. The pale green powder is insoluble in water. C. Fromherz obtained an analogous product by calcining a mixture of manganese dioxide with twice its weight of strontium nitrate—*vide infra*. V. Auger and M. Billy said that the **calcium manganate**, $CaMnO_4$, obtained by P. F. Chevillot and W. F. Edwards, G. Forchhammer, C. Fromherz, and E. Delaurier by calcining an intimate mixture of manganese dioxide and slaked lime or chalk is impure. It is insoluble in water, and gives off oxygen when heated—*vide infra*. A. F. Jolles obtained a basic **cadmium manganate**, $CdMnO_4.H_2O$, by the action of an excess of ammonia and potassium manganate on a soln. of a cadmium salt. According to A. Gawalowsky, **mercurous manganate** is probably formed as a black precipitate when an alkali permanganate in an alkaline soln. is treated with mercury ; W. Kirchmann said that mercurous and mercuric oxides are formed ; and D. Borar represented the reaction : $2KMnO_4 + 3Hg + H_2O = 3HgO + 2MnO_2 + 2KOH$. J. W. Retgers could not prepare **thallous manganate** on account of the oxidation of thallous to thallic salts by potassium manganate. A. F. Jolles obtained **lead manganate,** $PbMnO_4.2H_2O$, as a chocolate-brown powder by the action of cold soln.

of eq. proportions of lead acetate and potassium permanganate. J. B. Hannay could not prepare it by the action of nitric acid and potassium chlorate on mixed soln. of manganous and lead salts. A. F. Jolles found that lead manganate loses its water at 150°, and that it is a strong oxidizing agent.

For the **manganous manganates** of A. Guyard, *vide supra*. V. Auger and M. Billy prepared a series of *manganimanganates* or **manganitomanganates** of the type $3RO.MnO_2.MnO_3.H_2O$, or $R_3Mn_2O_8.H_2O$, by fusing at 180° to 250° mixtures of a hydroxide of an alkaline earth, sodium and potassium nitrates, and potassium permanganate. The salts are said to be constituted: $HO.R.O.MnO.O.R.O.$ $MnO_2.O.R.OH$. J. Holluta found that manganitomanganate is probably an intermediate product in the reduction of the manganates by formic acid. The absorption spectra of manganates and manganitomanganates are different. The basic barium manganate of A. Rosenstiehl is thought by V. Auger and M. Billy to be **barium manganitomanganate,** $Ba_3Mn_2O_8.H_2O$, and it can be made by the general method as a green insoluble powder which can be heated to redness without losing its combined water. The corresponding **strontium manganitomanganate,** $Sr_3Mn_2O_8.H_2O$, is probably the same as the products reported by P. F. Chevillot and W. F. Edwards, and C. Fromherz—*vide supra*. Similarly also with the calcium manganate cited above, which V. Auger and M. Billy regarded as identical with **calcium manganitomanganate,** $Ca_3Mn_2O_8.H_2O$. By working in an analogous manner, insoluble **lithium manganitomanganate,** $Li_3Mn_2O_8.H_2O$, was obtained.

§ 14. Permanganic Acid

P. F. Chevillot and W. F. Edwards [1] observed that on adding a little water to a soln. of potassium permanganate in conc. sulphuric acid, a violet vapour is given off which soon condenses and decomposes; O. Unverdorben also observed that if the permanganate be warmed with a little conc. sulphuric acid, the red vapour which is evolved attacks the lungs, and readily decomposes in the absence of water into manganese dioxide and oxygen; it forms a red soln. with water. L. Hünefeld found that it can be distilled from a conc. sulphuric acid soln. of the permanganate at 130°, and the vapour condenses to carmine-red needles, which are decomposed by water into manganic oxide and sulphuric acid. L. Gmelin said that if the permanganate is quite free from chlorine, no red vapour is produced under these conditions. F. Wöhler observed that when conc. sulphuric acid is poured over the crystals of potassium permanganate, the salt is decomposed with explosive violence and the evolution of much heat, and even flame. A cloud of finely-divided manganese oxide is also produced, and there is a copious evolution of oxygen. F. Wöhler hence concluded that permanganic acid is a gas which, at the moment of its liberation, is decomposed by the heat of the reaction into oxygen and manganese dioxide. T. E. Thorpe and F. J. Hambly, and B. Franke added that the permanganate here employed probably contained some chlorate or perchlorate, because the purified and dry salt dissolves quietly in conc. sulphuric acid without any great rise of temp. According to H. Aschoff, if conc. sulphuric acid be used, a clear, sage-green soln. is produced, and if the monohydrated acid be employed, the soln. is dark brown and it contains a number of oily drops which gradually

sink to form a very unstable, dark reddish-brown liquid which does not solidify
at −20°. H. Aschoff analyzed this reddish-brown liquid, and he obtained data
in accord with the assumption that it is a compound, **manganese heptoxide**, or
permanganic anhydride, Mn_2O_7. H. Aschoff prepared this compound by adding
to well-cooled sulphuric acid of sp. gr. 1·845, in small quantities at a time, potassium
permanganate, free from chlorine. The dark olive-green liquid forms oily drops
of manganese heptoxide, which settle to the bottom as a dark reddish-brown liquid.
Up to about 20 grms. of the permanganate can be employed without danger.
J. M. Lovén, and A. Terreil used a similar process. P. Thénard prepared what he
regarded as anhydrous permanganic acid, and A. Terreil also regarded as per-
manganic acid the greenish-black, oily drops of liquid which he obtained by the
action of moisture or a small proportion of water on a soln. of permanganate in
sulphuric acid. The product was probably the anhydride. Observations on the
action of sulphuric acid on permanganate were also made by M. Spiess, H. Kolbe,
R. Böttger, J. Personne and M. l'Hermite, and E. Delaurier.

B. Franke, from indirect evidence, inferred that the dark green soln. obtained
by the action of sulphuric acid on potassium permanganate contains manganic
oxysulphate, $(MnO_3)_2SO_4$, formed in accord with $2KMnO_4+H_2SO_4=K_2SO_4$
$+2HMnO_4$, and $2HMnO_4+H_2SO_4=(MnO_3)_2SO_4+2H_2O$. The argument was based
mainly on the existence of the analogous oxyfluoride, MnO_3F, and the oxychloride,
MnO_3Cl; and the difference in the colours of the soln. obtained by the use of
concentrated and monohydrated sulphuric acids—*vide supra*—corresponds with
the assumed difference in the chemical nature of the soln. T. E. Thorpe and
F. J. Hambly continue : On adding a small quantity of water to the well-cooled
green soln., manganese heptoxide is produced in accord with B. Franke's equation :
$(MnO_3)_2SO_4+H_2O=H_2SO_4+Mn_2O_7$. This accounts for the production of the
heptoxide by the use of monohydrated sulphuric acid and its non-formation
when the conc. acid is employed. According to T. E. Thorpe and F. J. Hambly,
if potassium permanganate be added in small quantities at a time to pyrosulphuric
acid, or to sulphuric acid to which sulphur trioxide has been added, as each
successive portion of the salt reaches the acid, flames are emitted, together with a
cloud of sulphur trioxide, darkened in colour by particles of manganese dioxide.
The soln. obtained is of a lavender-blue colour, and on standing deposits a pink-
coloured salt ; this on treatment with cold water forms a deep brown soln. which
ultimately deposits brown oxide of manganese. If the dark green soln. of potassium
permanganate in sulphuric acid be cautiously heated in a current of air, the violet
gaseous substance which is given off, and which condenses to a dark red, viscid
mass, was considered by A. Terreil to be permanganic acid, $HMnO_4$, but H. Aschoff
showed that it is also produced by the gradual decomposition of the heptoxide,
which contains no hydrogen. As indicated above, B. Franke, and T. E. Thorpe
and F. J. Hambly considered it to be manganese trioxide, MnO_3, while F. R. Lank-
shear regarded it as impure permanganic acid.

H. Aschoff described manganese heptoxide as a dark reddish-brown, oily liquid ;
A. Terreil said that its colour is greenish-black ; while J. M. Lovén said that its
colour is yellowish-green, and its sp. gr. 2·4. D. Balareff discussed the mol. vol.
He also gave for the heat of soln. $(Mn_2O_7,Aq)=(2HMnO_4,Ag)+12$ Cals. A. Simon
and F. Feher gave for the dissociation press., p mm., of the heptoxide :

p	0°	2°	6°	10°	14°	21°
	0·5	1·2	3·2	7·0	147·0	593 mm.

The heats of the reactions are $(2Mn,3\frac{1}{2}O_2)=170$ Cals. ; and $Mn_2O_7\rightarrow2MnO_2+1\frac{1}{2}O_2$
$+82$ Cals. A. Terreil thought that it formed a violet vapour with an unpleasant
metallic odour. According to H. Aschoff, the liquid does not solidify at −20°, and it
is apparently non-volatile, because it may be heated under reduced press. to 60°–65°
without the slightest evolution of vapour, but at higher temp. it is decomposed with
a sudden and violent explosion into oxygen and manganic oxide. The rapidity of

the explosion is attributed to the action of the separated manganic oxide, since P. Thénard has shown that a minute quantity of manganic oxide instantly resolves the heptoxide, even in the cold, into oxygen and manganese dioxide. P. Thénard said that the heptoxide detonates at 30° to 40°, with the formation of oxygen and manganese dioxide. A. Terreil also noted that it decomposes when rapidly heated, and when slowly heated its temp. cannot be raised above 60° or 70°. J. M. Lovén also noted the formation of manganese dioxide when the heptoxide explodes. H. Aschoff found the heptoxide to be extremely unstable, and it slowly evolves ozonized oxygen ; as the bubbles of gas burst at the surface of the liquid, they form a violet cloud. P. Thénard, and A. Terreil noted that the heptoxide smells of ozone. J. M. Lovén added that in dry air the heptoxide can be kept many days, but in moist air it forms a violet vapour—*vide supra*. H. Aschoff observed that a drop of the heptoxide in hydrogen decomposes explosively ; and that in air it is very hygroscopic, and is gradually decomposed by the absorbed moisture ; when it is dropped into water it dissolves, forming a purple liquid, with the evolution of so much heat that it suffers partial decomposition, and the aq. soln., even when dilute, is gradually decomposed by heat into manganese dioxide and oxygen. The heptoxide decomposes by contact with sulphur, and likewise in hydrogen sulphide. It dissolves in conc. sulphuric acid without decomposition, forming an olive-green or sage-green soln.—*vide supra*. A. Terreil said that the soln. in a mol of sulphuric acid diluted with three mols of water is violet ; while there is a vigorous reaction, accompanied by light, when the heptoxide is put in contact with a few drops of a soln. of potassium sulphite. H. Aschoff found that phosphorus in contact with the heptoxide produces a violent explosion. There is also a detonation when the heptoxide is brought in contact with carbon, carbon disulphide, and with many organic substances—*e.g.* paper, ethylene, alcohol, and ether. J. F. Durand observed that the green soln. of manganese heptoxide in conc. sulphuric acid oxidizes diamond, graphite, and acetylene-black quantitatively in the cold, at different rates, to form carbon dioxide. C. A. Winkler made some observations on the reaction with ether. A. Terreil observed an explosion occurs when the heptoxide is brought in contact with fats. J. M. Lovén observed that it forms a cherry-red soln. with acetic acid. According to R. Böttger, a mixture of 2 parts of dry potassium permanganate and 3 parts of conc. sulphuric acid gives off ozonized oxygen on standing for a week, and it is a powerful oxidizing agent ; for instance, a couple of drops of the mixture in contact with a couple of drops of the following oils produce an explosion or else inflammation : nutmeg, rue, citron, cloves, marjoram, cubeb, and spikes, and with oil of thyme, and turpentine ; while methyl and ethyl alcohols, carbon disulphide, ether, ethylene chloride, benzene, coal-gas, paper, and cotton inflame without explosion ; and gun-cotton and gunpowder are not inflamed. P. Thénard, and H. Aschoff observed that silver oxide, mercuric oxide, and manganese dioxide decompose manganese heptoxide in the cold.

Soln. of manganese salts are readily oxidized to pink or violet permanganates, or **permanganic acid,** $HMnO_4$. Thus, G. Forchhammer oxidized manganous sulphate by digesting it with lead dioxide and sulphuric acid. W. Crum, and J. Volhard recommended nitric in place of sulphuric acid. The reaction was studied by T. M. Chatard, S. Peters, P. Pichard, A. Leclerc, L. L. de Koninck, T. E. Thorpe and F. J. Hambly, A. Ledebur, F. C. G. Müller, V. Deshayes, F. Osmond, O. W. Gibbs, R. Parkinson, P. A. Meerburg, J. B. J. D. Boussingault, and C. F. Schönbein. G. Forchhammer treated a green soln. of potassium manganate with lead nitrate, and the precipitate of manganese hemitrioxide and lead dioxide—after washing but not drying—was decomposed by prolonged digestion with dil. sulphuric acid (1 : 10), not in sufficient quantity to saturate the lead oxide. C. Fromherz objected that most of the permanganic acid would be decomposed after the sulphuric acid had been saturated with lead oxide. Oxidizing agents other than lead dioxide can be employed. Thus, L. Schneider, L. Dufty, J. Red drop and H. Ramage, F. Ibbotson and H. Brearley, H. Ramage, A. A. Blair,

R. S. Weston, F. J. Metzger and L. E. Marrs, F. J. Metzger and R. F. McCrackan, P. H. M. P. Brinton, W. F. Hillebrand and W. Blum, C. D. Braun, D. J. Demorest, J. R. Cain, G. Bertrand, H. Rubricus, R. A. Gortner and C. O. Rost, and H. F. U. Little recommended oxidation with sodium bismuthate or bismuthic acid; and H. E. Walters, H. Marshall, M. R. Schmidt, H. Baubigny, H. Rubricus, A. Travers, J. Heslinga, J. Oesch, H. Kunze, P. Holland, J. J. Boyle, and M. Stanichitch recommended ammonium persulphate. A. Travers studied the oxidation of manganous salts to permanganate by ammonium persulphate in the presence of silver nitrate: $7AgNO_3+3(NH_4)_2S_2O_8+6H_2O \rightleftharpoons 3Ag_2O_2.AgNO_3 +3(NH_4)_2SO_4+3H_2SO_4+6HNO_3$. The silver peroxynitrate acts as a catalyst. Thus if 10 per cent. of acid is previously added to the silver nitrate, the silver compound is produced in a black, colloidal form; the manganous salt upsets the equilibrium, which is restored gradually, the liquid appearing wine-red in colour owing to the superposition of the violet of the permanganic acid on the black silver compound. A further addition of manganous salt again reverses the reaction, and the true violet of the permanganic acid is seen, followed by the above changes. O. Kühling used silver peroxide and nitric acid as oxidizing agent. According to C. F. Schönbein, soln. of manganese salts in contact with air and phosphorus become columbine-red owing to the formation of permanganic acid by oxidation by the ozone which is formed; so also is permanganic acid formed if a manganese salt and phosphorus be shaken with ozonized air, chlorine-water, or bromine-water. H. Trommsdorff discussed the influence of manganic phosphate on the colour.

According to A. A. Maximoff, sodium and potassium permanganates decompose in alkaline soln. somewhat as typified by the equations: $2KMnO_4+2KOH =2K_2MnO_4+H_2O+\frac{1}{2}O_2$; and $K_2MnO_4+H_2O=MnO_2+2KOH+\frac{1}{2}O_2$. When a permanganate is formed by the fusion of an alkali hydroxide with manganese dioxide, the presence of an alkali dioxide assists the reaction. It is supposed that even when no dioxide is added, some is formed during the reaction. In these circumstances, whereas cæsium, potassium, rubidium, and sodium should form the manganate and permanganate on fusion of their hydroxides with manganese dioxide, lithium, which does not form a dioxide, should not undergo the reaction. This has been found to be the case. Lithium permanganate could be formed only by the addition of lithium sulphate to barium permanganate. Under the conditions in which potassium permanganate gave the manganate in potassium hydroxide soln., lithium permanganate in lithium hydroxide soln. does not change, except exceedingly slowly, a change which is attributed to the presence of sodium in the glass of the containing vessel. Hydrogen dioxide so accelerates the reaction that no manganate and only manganese dioxide is formed. The reaction has been carried out quantitatively by titrating standard soln. of the permanganates with hydrogen dioxide until (i) a green colour is formed and (ii) a grey precipitate appears. This has been accomplished for lithium as well as for potassium. The results obtained are in accord with the equations: (i) $2M'MnO_4+H_2O_2+2M'OH =2M'_2MnO_4+2H_2O+O_2$; (ii) $2M'_2MnO_4+2H_2O_2=2M'_2O+2H_2O+2MnO_2+2O_2$. Sodium permanganate in the presence of sodium dioxide undergoes the change: $2Na_2MnO_4+2Na_2O_2+4H_2O=2MnO_2+8NaOH+2O_2$. As shown by O. Dieffenbach, the reaction is reversed in the presence of potassium ferricyanide. The reaction was brought about by adding dry sodium hydroxide to a little water, heating the mixture to boiling, and adding dry manganese dioxide. On adding sodium dioxide to the mixture, a gas is evolved and sodium manganate is formed. The reactions involving the oxidation and reduction of manganese salts are as follow: $MnO_2+4KOH+O_2=MnO_2(OK)_2+KO\cdot OK+2H_2O$; $2KMnO_4+K_2O_2 = 2MnO_2(OK)_2+O_2$; $MnO_2(OM')_2 + HO\cdot OH = O_2 + Mn(OH)_2(OM')_2 = H_2MnO_3 +M'_2O+O_2$.

According to H. Aschoff, if manganese heptoxide be dropped into water it gradually dissolves to form a violet soln. The heat developed may decompose part of the permanganic acid—*vide supra*. J. M. Lovén added that decomposition

occurs only if the soln. be too concentrated, but soln. with 20 per cent. $HMnO_4$ can be so prepared. E. Mitscherlich obtained what he regarded as permanganic acid by adding an eq. quantity of dil. sulphuric acid to a soln. of barium per-manganate. M. M. P. Muir allowed the soln. to stand a few days, filtered it through glass-wool, and concentrated it in vacuo over sulphuric acid. E. Mitscherlich said the soln. decomposes at 30°–40°. H. Aschoff used a similar process. Accord-ing to R. Rusconi, when 30 per cent. sulphuric acid, containing a small proportion —say 0·05 per cent.—of manganous sulphate, is electrolyzed in a U-shaped vessel using a potential difference of 5 to 6 volts, the formation of traces of permanganic acid at the anode is observable after a few minutes. If, however, the soln. contains also a few drops of sat. silver sulphate soln., the formation of permanganic acid at the anode is immediate and rapid. Similar results are obtained if the sulphuric acid is replaced by conc. sodium hydrosulphate soln. The oxidation is probably effected through the intermediate formation of a persulphate (q.v.).

M. M. P. Muir obtained better results by this process than by treating an eq. amount of soln. of silver permanganate and hydrochloric acid, filtering off the silver chloride, and evaporating in vacuo. L. Hünefeld recommended decomposing the barium permanganate with phosphoric acid, but the product is then impure. R. E. Wilson and co-workers obtained barium permanganate or manganate by the action of barium peroxide on manganese dioxide and fused alkali hydroxide. C. Fromherz recommended passing carbon dioxide into water with barium manganate in suspension, and kept agitated, until the green powder becomes brown. The decanted violet soln., containing permanganic acid and barium acid permanganate and acid carbonate, is boiled for 15 mins. to expel the carbon dioxide and precipitate barium carbonate. The small quantity of barium salt still in soln. is removed by adding a few drops of dil. sulphuric acid. The soln. is decanted, boiled down to three-fourths of its vol., and decanted from the precipitated hydrated manganese dioxide. If the soln. is evaporated in vacuo, over sulphuric acid, brown manganese oxide is obtained ; but if evaporated at a gentle heat, the soln. on cooling deposits carmine-red needles with 8·411 per cent. of water. E. Mitscherlich objects that the boiling would decompose permanganic acid, and the product was possibly barium hydropermanganate, because crystals of permanganic acid cannot be so obtained.

L. von Putnoky and B. von Bobest studied the anodic oxidation of soln. of manganous salts in hydrofluoric acid. In the anodic oxidation there is first formed a brown oxidation product, which is manganese trifluoride ; and this then gives place to permanganic acid. No manganese tetrafluoride could be detected in the soln. F. W. Skirrow, and E. Müller and P. Koppe obtained only the brown soln., not permanganic acid ; and M. G. Levi and F. Ageno, permanganic acid. F. Förster, indeed, said that " in the presence of hydrofluoric acid, manganous sulphate passes only into a manganic salt, because there is a strong inclination of the fluoride to form a complex with tervalent manganese, and this prevents the oxidation going further." L. von Putnoky and B. von Bobest observed that the permanganic acid can exist in the soln. only when the whole of the manganous salt has been converted into manganic salt, since, according to E. Müller and P. Koppe, any permanganic acid formed is decomposed : $HMnO_4 + 4MnF_2 + 7HF = 5MnF_3 + 4H_2O$. According to L. von Putnoky and B. von Bobest, permanganic acid is the primary product of the reaction, and so long as any manganous fluoride is present in the soln., it is converted into manganese trifluoride. The trifluoride is therefore a secondary product of all the reactions. When the manganous fluoride is all destroyed, the permanganic acid remains, and it increases in amount only at the cost of the manganese trifluoride.

H. N. Morse and J. C. Olsen electrolyzed a conc. soln. of potassium perman-ganate contained in a porous pot arranged so that the hydrogen formed at the cathode cannot reduce the soln., and that the alkali hydroxide also formed at the cathode can be removed. M. M. P. Muir said that the acid can be obtained in violet-blue, crystalline needles contaminated with manganese oxides. In order to obtain a fair proportion of the crystals, it is necessary to allow small quantities of a moderately conc. soln. of the acid to evaporate in the air ; if large quantities of the soln. are used, the evaporation proceeds so slowly that most of the acid has decom-

posed when the evaporation is finished. The evaporation should proceed under a beaker, not in a desiccator.

According to H. N. Morse and J. C. Olsen, when an aq. soln. of permanganic acid is evaporated to dryness over sulphuric acid in vacuo, a shining black solid, $MnO.20MnO_2$, is obtained. When an aq. soln. of the acid is kept in an open vessel, it gradually deposits brown, pasty solid matter, 6 to $10MnO.20MnO_2$. The aq. soln. of permanganic acid appears dark carmine-red by reflected light, and by transmitted light dark violet, or with greater dilution, reddish-blue or carmine-red. The spectrum was examined by F. Hoppe-Seyler, G. C. Stokes, R. T. Simmler, J. Müller, etc.—*vide supra*. C. F. Schönbein suggested that permanganic acid is really a compound of manganese dioxide and hydrogen dioxide or ozone, because with reducing agents it behaves like hydrogen dioxide or ozone itself. J. M. Lovén, and H. N. Morse and J. C. Olsen obtained concordant results for the **electrical conductivity** of aq. soln., λ mhos, at 25°, containing a mol of the acid in v litres :

v	.	2	4	8	16	32	64	128	256	512	1024
λ	.	336	354	371	377	385	392	398	403	403	400·1

The results indicate that the acid is strong and monobasic. E. Franke observed that the strength of the acid is about equal to that of nitric acid, but it is unstable and easily decomposed, so that his observations show a rapid fall in the conductivity of the soln. with dilution. J. M. Lovén calculated 0·89 for the avidity of the acid. C. M. Bradbury reviewed the evidence in support of the thesis that permanganic acid is monobasic. C. Fromherz found that the acid has just a sweet taste, which afterwards appears rough and bitter ; while G. Forchhammer said that the taste is pungent and disagreeable. C. Fromherz found that the acid stains the skin brown, but does not redden litmus ; while G. Forchhammer, and E. Mitscherlich added that the acid destroys the colouring matter of litmus and turmeric, at the same time turning them brown owing to the deposition of hydrated manganese dioxide.

O. Sackur, and O. Sackur and W. Taegener calculated the normal **potential** for the reduction of *permanganates to manganese dioxide* in alkaline soln. : $MnO_4'+2H_2O=MnO_2+4OH'+3F$ from the measurements of J. K. H. Inglis of the e.m.f. of the cell (Pt) : $MnO_2,KMnO_4.H_2SO_4$: $KCl_{sat. soln.}$: $0·1N$-KCl : Hg_2Cl_2 : Hg, at room temp. They found for normal alkaline soln., $[OH']=1$, $E_H=0·54$ volt, and for soln. of different concentration $E_H=0·54+0·019 \log [MnO_4']-0·077 \log [OH']$ volt. For acid soln., $MnO_4'+4H'=MnO_2+2H_2O+3F$, $E_H=1·63$ volt, for normal acidity, $[H']=1$, and for other concentrations $E_H=1·63+0·019 \log [MnO_4']+0·077 \log [H']$ volt. From these values, and the results for the potential of the reduction from *permanganate to manganese monoxide*—*vide supra*—it follows that for the change $MnO_4'+8H'=Mn''+4H_2O+5F$, for normal soln., $E_H=1·52$ volt, and for other concentrations $E_H=1·52+0·012 \log [MnO_4']-0·012 \log [Mn'']+0·093 \log [H']$ volt. O. Sackur also calculated the **free energy** of the passage from *permanganate to manganese dioxide*. Since for $4(MnO_4'+4H'=MnO_2+2H_2O+3F)$, $E_H=1·63$ volt, when the potential for the liberation of oxygen is greater than is the case with water, for which $3(2H_2O+4F=O_2+4H')$, $E_H=1·23$ volt, then for $4MnO_4'+4H'=4MnO_2+2H_2O+3O_2$, $E_H=0·40$ volt, and the free energy of the reaction is $Q=12F(0·4+0·019 \log [MnO_4']+0·019 \log [H']-0·0145 \log p_{O_2})$ joules. The latent pressure of the oxygen, so to speak, is unity when the reacting constituents have unit concentration, and $\log p_{O_2}=27·6+1·3 \log [MnO_4']+1·3 \log [H']$, or $p_{O_2}=10^{27·6}$. Similarly, the free energy of the passage from *permanganate to a manganous salt* is calculated from $4(MnO_4'+8H'=Mn''+4H_2O+5F)$ when $E_H=1·52$ volt, and $5(2H_2O+4F=O_2+4H')$ has $E_H=1·23$ volt, so that $4MnO_4'+12H'=4Mn''+6H_2O+5O_2$, and $E_H=0·29$ volt. Consequently, $20F(0·29+0·012 \log [MnO_4']+0·012 \log [Mn'']+0·035 \log [H']+0·0145 \log p_{O_2})$ joules, and the latent pressure of the oxygen is $\log p_{O_2}=20+0·8 \log [MnO_4']-0·8 \log [Mn'']+2·4 \log [H']$, so that for unit concentrations $p_{O_2}=10^{24}$

atm. In both cases the tendency for the permanganate to give off oxygen increases with increasing acidity of the soln. The **oxidizing potentials** E_H normal acid soln., when $[H^\cdot]=1$, given by O. Sackur, are: $MnO_4'\rightarrow MnO_4''$, 0·61 volt; $O_2\rightarrow H_2O$, 1·23 volts; $MnO_2\rightarrow Mn^{\cdot\cdot}$, 1·35 volts; $MnO_4\rightarrow Mn^{\cdot\cdot}$, 1·52 volts; $MnO_4'\rightarrow MnO_2$, 1·63 volts; and $MnO_4''\rightarrow MnO_2$, 2·12 volts. Similarly, for normal alkaline soln., when $[OH']=1$, they are: $O_2\rightarrow OH'$, 0·41 volt; $MnO_4''\rightarrow MnO_2$, 0·50 volt; $MnO_4'\rightarrow MnO_2$, 0·52 volt; and $MnO_4'\rightarrow MnO_4''$, 0·61 volt. The results show that in acidic and alkaline soln. manganese dioxide, manganate, and permanganate have a stronger latent oxygen pressure than oxygen itself at 1 atm. press. From the e.m.f. of the cell $H_2 \mid HClO_4 \mid HClO_4, KMnO_4 \mid MnO_2$, at 25°, D. J. Brown and R. F. Tefft calculated the oxidation potential of $MnO_4'+4H^\cdot+3\oplus=MnO_2+2H_2O$ to be 1·586 volts. This value decreases with increasing acid conc. C. E. Ruby obtained $MnO_2+4OH'+2\oplus=MnO_4''+2H_2O$, −0·664 volt; $MnO_2+4OH'+3\oplus=MnO_4'+2H_2O$, −0·647 volt; and $MnO_2+2H_2O+3\oplus=MnO_4'+4H^\cdot$, −1·757 volts.

According to C. Fromherz, the aq. soln. of permanganic acid is decomposed when exposed to **light** and hydrated manganese dioxide is precipitated; the soln. is also decomposed by **heat.** Thus the decomposition is partial at 45° and complete at 100°. The evidence is not all concordant. C. Fromherz reported the decomposition to be faster the smaller the concentration of the soln., and a conc. soln. may be boiled for many hours without sensible decomposition. E. Mitscherlich observed that the soln. slowly decomposes at about 20°, and rapidly at 30° to 40°, giving off oxygen and precipitating hydrated manganese dioxide. The decomposition is completed by boiling. J. M. Lovén said that soln. with 0·5 to 1·0 per cent. $HMnO_4$ are very stable and can be boiled without loss of oxygen; and the soln. can be concentrated by boiling or by freezing. H. Aschoff observed that when the soln. is evaporated to dryness on a water-bath, oxygen and hydrated manganese dioxide are produced—*vide supra* for M. M. P. Muir's observations. C. F. Schönbein observed that the presence of finely divided platinum accelerates the decomposition of the soln. to hydrated dioxide, water, and oxygen. G. Forchhammer detected what he called an electrical odour—possibly ozone—when the soln. is evaporated or exposed to sunlight; and C. C. Frye added that when a 22 per cent. soln. is distilled with sulphuric acid some ozone is given off.

According to C. Fromherz, and F. Jones, **hydrogen** rapidly reduces a soln. of permanganic acid, forming water and hydrated manganese dioxide—*vide infra*, potassium permanganate; and F. Duran observed that it adsorbs hydrogen, and **oxygen.** H. Aschoff, and B. C. Brodie observed that **hydrogen dioxide** reduces permanganic acid completely at ordinary temp. and in the presence of an excess of acid: $2HMnO_4+5H_2O_2=2MnO+6H_2O+5O_2$; and, added P. Thénard, the decomposition occurs at a low temp. without the evolution of oxygen, and M. Berthelot suggested that at −12° the trioxide, H_2O_3, is formed and it decomposes at a higher temp. A. Gorgeu added that permanganic acid is reduced by hydrogen dioxide to a manganous salt not only in the presence of acids, but also in the presence of other substances which can dissolve manganous oxide —*e.g.* a soln. of ammonium chloride. If free acid be not present, and hydrogen dioxide be slowly added to the dil. soln., the reaction can be symbolized: $Mn_2O_7+3H_2O_2=2MnO_2+3H_2O+3O_2$, and if more hydrogen dioxide be added, the manganese dioxide is itself reduced—*vide infra*, potassium permanganate.

C. Fromherz observed that permanganic acid is not decomposed by **chlorine**; and J. Brown found that the reaction with **hydrochloric acid** can be symbolized: $HMnO_4+7HCl=MnCl_2+4H_2O+5Cl$, but the amount of permanganic acid consumed is greater than corresponds with this equation unless the liberated chlorine be removed. The reaction was also studied with respect to titrations with permanganate in the presence of hydrochloric acid, by J. Löwenthal and E Lenssen, C. R. Fresenius, J. Wagner, etc. The effect of manganous salts was examined by J. L. C. Zimmermann, of hydrofluoric acid, potassium fluoride, potassium sulphate, or sodium sulphate, by H. Rose, and barium chloride, by J. Wagner.

The catalytic effects of ferrous, chromium, cadmium, and manganous salts, platinum tetrachloride, and auric chloride were discussed by W. Ostwald, and J. Wagner. C. W. Hempel, and W. Lindner found that **potassium bromide** does not decompose permanganic acid in neutral soln., but in sulphuric acid soln. the **hydrobromic acid** is decomposed, slowly in the cold, rapidly when heated, and bromine is set free. C. Fromherz found that **iodine** is oxidized by permanganic acid to iodic acid; a little **hydriodic acid** is decomposed, forming iodine and hydrated manganous oxide, but if much iodide be present, some soluble manganous iodide is formed. C. F. Schönbein also noticed that **potassium iodide** forms some iodate, with the separation of iodine and of a brown hydrated manganese oxide. R. Espenchied represented the reaction with a hydrochloric acid soln. of potassium iodide by the equation : $HMnO_4 + 5KI + 7HCl = MnCl_2 + 5KCl + 4H_2O + 5I$. C. F. Rammelsberg observed that permanganic acid has no action on **bromic acid.**

C. Fromherz said that **sulphur** is oxidized in a few days to sulphuric acid; a little **hydrogen sulphide** colours the soln. brown, and a brown hydrated oxide is soon deposited, while an excess of hydrogen sulphide forms milk of sulphur, water, and sulphuric acid. C. F. Schönbein added that the **metal sulphides** are oxidized to sulphates. C. Fromherz found that **sulphur monochloride** separates sulphur and forms manganous sulphate; and **sulphurous acid** is oxidized to sulphuric acid. F. Duran observed that sulphur dioxide is adsorbed by the salt. L. P. de St. Gilles added that some dithionic acid is formed when sulphurous acid acts on permanganic acid, while **thiosulphuric acid** forms sulphuric and dithionic acids. C. Fromherz observed that **sulphuric acid** does not decompose permanganic acid. F. Jones, and B. Brauner observed the evolution of oxygen from soln. of potassium permanganate and sulphuric acid during oxidation effected by their means. F. A. Gooch and E. W. Danner found that the decomposition of the permanganate by sulphuric acid increases with the amount of acid present, the time of action, and increase of temp. A 20 per cent. soln. of sulphuric acid produces no appreciable effect at ordinary temp. and under exposures of a few hours only. In five days, however, a very considerable action takes place at the ordinary temp., and heating the mixture of acid and permanganate to 80° for an hour and a half is closely comparable in its effect with that brought about by the five days' action at the ordinary temp. The change is brought about by a tendency towards reduction on the part of the acid. When the acid is not present in proportions greater than 50 per cent. of the mixture, in the early stages of the action the oxygen lost by the permanganate is liberated, but later on the decomposition of the permanganate results in the precipitation of manganese in the form of a higher oxide, or in the retention of the manganese in soln. in the form of a higher sulphate.

F. Duran found that **nitrogen** is adsorbed by the salt. According to C. F. Schönbein, an excess of **ammonia** is oxidized to ammonium nitrite when shaken with platinum sponge and permanganic acid; the reaction proceeds slowly in the cold and rapidly when heated. The soln. of permanganic acid is slowly decolorized by **nitric oxide**, and by **hyponitrous acid,** while C. Fromherz, and L. P. de St. Gilles found that **nitrous acid** immediately forms manganous nitrate. F. Duran observed that nitrous and nitric oxides are absorbed by the salt. C. Fromherz observed no reaction with **nitric acid.** C. Fromherz found that **phosphorus** is gradually oxidized to phosphoric acid by permanganic acid; and similarly also with **phosphine.** L. P. de St. Gilles said that **hypophosphorous acid** is not completely oxidized to phosphoric acid. T. Salzer found that **hypophosphoric acid** is oxidized to phosphoric acid. C. Fromherz observed no reaction with **phosphoric acid.** H. B. Parsons found that **arsine** is oxidized by permanganic acid to arsenious and arsenic acids; C. Fromherz, and L. P. de St. Gilles, that **arsenic trioxide** is oxidized to the pentoxide, while **arsenic pentoxide** has no action. Permanganic acid is slowly decomposed by **antimony,** forming antimony oxide; and **antimony trioxide** is converted into the higher oxide. H. Rose observed that **antimony trichloride** reduces permanganic acid; and C. Fromherz found that **bismuth** is

slowly oxidized by the permanganate. B. W. Gerland found that **vanadyl salts** are oxidized to vanadates.

C. Fromherz observed that **boric acid** has no action on permanganic acid, while recently ignited **carbon** rapidly decomposes the acid without developing a gas. According to J. F. Durand, amorphous carbon as acetylene black, graphite, and the diamond is quantitatively oxidized to carbon dioxide when treated in a finely divided condition with the green soln. of permanganic anhydride in conc. sulphuric acid. The reaction proceeds at ordinary temp. with different degrees of vigour in the three cases. F. Duran found that **carbon monoxide** is adsorbed by the salt and likewise also **carbon dioxide.** C. Fromherz observed that carbon dioxide has no chemical action. F. Duran observed that **methane, as** well as **ethane,** and **propane,** is adsorbed by the gas; **carbon disulphide** forms carbon dioxide and sulphuric acid; **potassium ferrocyanide** forms ferricyanide; **ethylene, alcohol,** and **ether** form carbon dioxide and water; O. Unverdorben said that **acetic acid** has no action, but L. Gmelin found that it acts very slowly, and that **oxalic acid** is oxidized to carbon dioxide and water. C. W. Hempel represented the reaction in the presence of sulphuric acid at 35° to 40° by: $2HMnO_4+5H_2C_2O_4+2H_2SO_4=2MnSO_4+10CO_2+8H_2O$. The influence of time, and the concentrations of the sulphuric acid, manganous sulphate, oxalic acid, and potassium permanganate were studied by A. V. Harcourt, A. V. Harcourt and W. Esson, A. Skrabal, R. Ehrenfeld, R. Luther, and N. Schiloff—*vide supra,* manganese dioxide. C. Fromherz observed that **tartaric acid** reduces permanganic acid, forming a manganous salt; similarly with **formic acid,** a reaction studied by N. Schiloff, and J. Holluta. A. Skrabal and J. Preiss found that the oxidation of formic acid occurs in stages as in the case of oxalic acid. There is an induction period. D. Vorländer and co-workers observed that in neutral or alkaline soln. most **amines** are oxidized by permanganates, but in acidic soln. the oxidation is accelerated. **Acyl derivatives** are comparatively stable in alkaline soln., but are more easily oxidized than the amines in acidic soln. Some **organic substances**—*e.g.* sugar, gum, wood, fibre, and paper—form carbon dioxide; other substances decompose the acid without evolving gas, but precipitating a brown manganese oxide—*e.g.* stearic and oleic acids, morphine, urea, the colouring matter of blood, gelatin, albumin, fibrin, indigo sulphate, and infusions of galls, saffron, logwood, madder, columbine, rhubarb, quassia, aloes, and Peruvian bark.

C. Fromherz observed that **tin** has no action on permanganic acid, but **zinc** and **iron** decompose the acid in a few days, while **copper, silver, mercury,** and **lead** decompose the acid in about four weeks. The metal is at the same time oxidized. C. F. Schönbein found that the action is rapid with finely-divided silver, and **platinum.** The action of permanganate on **cerous salts** is represented by the equation: $3Ce_2O_3+2KMnO_4+H_2O=6CeO_2+2KOH+2MnO_2$. The reaction is complete in the presence of mercuric or zinc oxides. The reaction has been utilized in the volumetric determination of cerium, and in separating cerium from lanthanum and didymium by F. M. Stapff. O. W. Gibbs, C. A. Winkler, F. Stolba, W. Muthmann and co-workers, C. James, G. P. Drossbach, P. E. Browning, R. J. Meyer and A. Schweitzer, C. R. Böhm, E. J. Roberts, L. Stützel, M. Esposito, C. von Scheele, and C. Fromherz observed that the acid is decomposed by **cuprous, mercuric, stannous, manganous, chromic, lead, and ferrous oxides or hydroxides** and usually a higher oxide is formed. H. N. Morse represented the reaction with **lead dioxide** and an acidified soln. of permanganic acid by the equation: $2HMnO_4+3PbO_2$ $=H_2O+2MnO_2+3PbO+3O_2$. H. N. Morse and co-workers, from their study of the reduction of permanganic acid by **manganese dioxide,** inferred: (i) Permanganic acid and potassium permanganate are reduced by precipitated manganese dioxide with the liberation of three-fifths of the active oxygen of the permanganic acid; (ii) the oxide produced by the complete reduction of a neutral soln. of potassium permanganate contains all the potassium of the original salt, and the supernatant liquid is therefore neutral; and (iii) whether the precipitated man-

ganese oxide is formed by the slow decomposition of a neutral soln. of potassium permanganate or by the addition of manganese sulphate to an acidified soln. of permanganate, the ratio of oxygen to manganese in it remains normal—that is, 2 : 1—only so long as unreduced permanganate or permanganic acid is present, otherwise the oxide loses oxygen, even at the ordinary temp. In the presence of permanganate, the lost oxygen is restored. Many oxidizable salts decolorize permanganic acid, forming manganous salts. F. Margueritte, for instance, observed this to occur with **ferrous salts ;** and H. Rose, with **mercurous nitrate, stannous chloride, cuprous chloride, and uranous salts.** I. Macagno observed that **molybdic salts** are oxidized to molybdates.

§ 15. The Permanganates

The general preparation of the permanganates is discussed in the preceding section in connection with permanganic acid. E. Mitscherlich[1] prepared **ammonium permanganate**, NH_4MnO_4, by treating silver permanganate with an eq. quantity of a soln. of ammonium chloride, filtering the liquid, and evaporating it for crystallization. H. Aschoff employed a similar process, and R. Böttger treated eq. proportions of barium permanganate and ammonium sulphate in a similar manner. O. T. Christensen modified a process also employed by R. Böttger in which 160 grms. of potassium permanganate were dissolved in 3 litres of water at 70°–80°, and a large excess (440 grms.) of ammonium chloride added; the soln. was evaporated to about 1600 c.c., decanted from the precipitated manganese oxide, and allowed to stand for 24 hrs. The crystals contained a little potassium salt even after two recrystallizations from water at 70°. E. Moles and M. Crespi treated soln. of 16 grms. of potassium permanganate in 300 c.c. of water at 70° with 44 grms. of ammonium chloride in 300 c.c. of water, concentrated the soln. to 200 c.c., and cooled it to 0°. G. Rapin used an electrolytic process.

The rhombic bipyramidal crystals were found by E. Mitscherlich to be isomorphous with the potassium salt, and to have the axial ratios $a:b:c$ =0·8141 : 1 : 1·31201; W. Muthmann gave 0·8164 : 1 : 1·3168. The (110)-cleavage.

is distinct. F. Rinne studied the crystals. T. V. Barker calculated the topic axial ratio to be $\chi : \psi : \omega = 3\cdot9768 : 4\cdot8711 : 6\cdot4113$. E. Moles and M. Crespi gave $2\cdot29$ for the sp. gr.; W. Muthmann gave $2\cdot2076$ for the sp. gr. and $62\cdot126$ for the mol. vol. I. I. Saslawsky gave $2\cdot29$ for the sp. gr. and calculated the contraction which occurs in the formation of the salt from its elements. When the salt is allowed to stand in a sealed tube exposed to diffuse daylight, it slowly decomposes, forming nitrogen oxides, ammonium nitrate, and a manganese oxide with a composition $MnO.22MnO_2.nH_2O$. W. Muthmann found that the dry salt is explosive; it sometimes detonates when rubbed in a mortar, developing a cloud of manganese dioxide and a smell of ozone. E. Moles and M. Crespi found that the salt explodes at $60°$. O. T. Christensen also observed that when the salt is heated to $58°$ or $60°$ it explodes in a few hours, forming nitrogen oxides and a manganosic oxide; if first heated slowly to between $42°$ and $46°$, and later to $50°$, the decomposition occupies some days. H. Aschoff found that 100 parts of water dissolve $7\cdot936$ parts of the salt at $15°$. E. Mitscherlich found that in the absence of an excess of ammonia, the aq. soln. can be evaporated without decomposition; but the salt easily decomposes when heated. W. Muthmann observed that the aq. soln. decomposes when boiled, giving off nitrogen, and forming hydrated manganese dioxide. O. T. Christensen observed that when the aq. soln. is boiled, it furnishes the same products as when the dry salt is heated, and in addition some nitrogen; and when the soln. is heated with ammonia, the decomposition products are nitrogen, ammonium nitrite, a little ammonium nitrate, and a hydrated oxide, $MnO.22MnO_2.28H_2O$, with some adsorbed ammonia. For the unit tetragonal cell of tetramethylammonium permanganate, $(CH_3)_4NMnO_4$, K. Herrmann and W. Ilge gave $a = 8\cdot439$ A., $c = 6\cdot019$ A.

E. Mitscherlich prepared **lithium permanganate**, $LiMnO_4.3H_2O$, from the soln. obtained by mixing soln. of silver permanganate and lithium chloride. A. A. Maximoff obtained the lithium salt by the action of lithium sulphate on barium permanganate—*vide supra*, permanganic acid; and E. Moles and M. Crespi, by mixing a soln. of $30\cdot8$ grms. of lithium perchlorate in 300 c.c. of water, and $30\cdot5$ grms. of potassium permanganate in 300 c.c. of water. The filtrate from the precipitated potassium perchlorate finally deposits lithium permanganate. The sp. gr. of the salt is $2\cdot06$, and it begins to decompose when heated to $190°$, with the evolution of oxygen. They found $K = 5\cdot10$ for the velocity of decomposition—*vide infra*, potassium permanganate. I. I. Saslawsky discussed the contraction which occurs in the formation of the salt from its elements. Its sp. gr. is $2\cdot6$. E. Mitscherlich said that the crystals are stable in air. H. Aschoff found that 100 parts of water at $16°$ dissolve $71\cdot43$ parts of the salt. E. Franke found the electrical conductivity, λ, of the aq. soln. with an eq. of the salt in v litres at $25°$ to be :

v .	. 32	64	128	256	512	1024
λ .	. $81\cdot79$	$84\cdot63$	$88\cdot22$	$90\cdot49$	$92\cdot81$	$95\cdot19$

When heated with an excess of lithium hydroxide, H. Aschoff found that the salt forms a manganate. A. A. Maximoff studied its deoxidation in alkaline soln.

P. F. Chevillot and W. F. Edwards observed that **sodium permanganate**, $NaMnO_4.3H_2O$, is formed when sodium manganate is dissolved in water; and H. Aschoff, that the salt is produced when silver permanganate is decomposed by a soln. of sodium chloride, the clear soln. evaporated over sulphuric acid, and the crystals dried on porous tiles. E. Moles and M. Crespi used a similar process. C. M. Tessié du Motay prepared a soln. of the salt by treating a soln. of sodium manganate with magnesium sulphate, in accord with the equation : $3Na_2MnO_4 + 2MgSO_4 + 2H_2O = 2Mg(OH)_2 + MnO_2 + 2Na_2SO_4 + 2NaMnO_4$. E. Köstermann and co-workers studied solid soln. with potassium perchlorate. E. Moles and M. Crespi said that the crystals of the monohydrate are hygroscopic. According to E. Schering, the commercial salt is really the potassium salt associated with

some of the sodium salt. The preparation of the salt was also described by J. Bendix, and E. Desclabissac. For electrolytic processes, *vide infra*, potassium permanganate. F. M. Raoult represented the composition oft he salt by $NaMnO_4$. $3H_2O$. I. I. Saslawsky discussed the contraction which occurs in the formation of the salt from its elements. Its sp. gr. is 2·47. P. F. Chevillot and W. F. Edwards observed that the crystals of the trihydrate are very deliquescent; E. Moles and M. Crespi found that the sp. gr. is 2·46, and that the salt decomposes with the evolution of oxygen at 170°. They found $K=0.111$ to 0.212 for the velocity of decomposition—*vide infra*, potassium permanganate. E. Franke found the eq. electrical conductivity, λ, of an aq. soln. with an eq. of the salt in v litres of water at 25° to be:

v .	.	64	128	256	512	1024
λ .	.	106·3	109·4	110·9	112·0	112·7

H. Aschoff observed that when sodium permanganate is boiled with a soln. of sodium hydroxide, some oxygen is evolved and a soln. of sodium manganate remains. A. A. Maximoff studied its deoxidation in alkaline soln. G. Gore, and E. C. Franklin and C. A. Kraus said that the salt is freely soluble in liquid ammonia.

P. F. Chevillot and W. F. Edwards prepared **potassium permanganate,** $KMnO_4$, by igniting a mixture of 1 part of manganese dioxide with 1 part of potassium hydroxide or 1·5 parts of potassium nitrate, dissolving the cold product in water, and evaporating the decanted red soln. for crystallization. Any manganate formed in the roasting process is converted into permanganate by hydrolysis: $3K_2MnO_4+2H_2O=MnO_2+4KOH+2KMnO_4$. In place of potassium nitrate, mixtures of potassium hydroxide and chlorate were recommended by G. Forchhammer, W. Gregory, F. Wöhler, R. Böttger, N. Gräger, and J. C. Sticht. In A. Béchamp's process 10 parts of manganese dioxide are mixed with 12 parts of potassium hydroxide, and water to make a pasty mass, and dried. The mixture is heated to dull redness in oxygen. The cold mass is extracted with water, and a current of carbon dioxide is passed into the soln. to convert any manganate into permanganate: $3K_2MnO_4+2CO_2=2K_2CO_3+MnO_2+2KMnO_4$. The soln. is then evaporated for crystallization. The process was also used by G. Forchhammer, J. Brock and F. Hurter, and G. Städeler. T. J. Pearsall observed that potassium permanganate is formed when a manganese salt is treated with chlorine and potash-lye; and G. Städeler converted manganate into permanganate by treating the soln. with chlorine: $2K_2MnO_4+Cl_2=2KCl+2KMnO_4$. L. E. Rivot and co-workers found that when manganese dioxide is suspended in alkali-lye at 40° to 50° and treated with chlorine, permanganate is formed. The process was examined by R. Böttger, W. Reinige, J. MacMullen, R. Phillip, E. Turner, R. J. Kane, J. B. van Mons, R. B. Stringfield, F. Krause, and W. Foster.

R. Wagner, and J. Heslinga used bromine in place of chlorine to convert the manganate into permanganate; F. Bayer used ozone: $2K_2MnO_4+O_3+H_2O=2KMnO_4+2KOH+O_2$. When a soln. of a manganous salt is treated with sodium hypochlorite, hydrated manganese dioxide is precipitated (*q.v.*), and on prolonged boiling, a small proportion of sodium manganate or permanganate is formed. M. Duyk showed that if the reaction occurs in the presence of copper salts, the copper is precipitated and permanganate is the main product. B. E. Dixon and J. L. White found that a small amount of sodium permanganate is formed even when special precautions are taken to purify both the manganese salt and the sodium hypochlorite, so the manganese dioxide itself appears to be capable of catalyzing the reaction. When present in quantities roughly equivalent to that of the manganese salt, the salts of several metals, notably copper, cobalt, nickel, and molybdenum (as molybdate), possess the property of greatly increasing the amount of permanganate formed in this reaction. In the presence of a copper salt the maximum amount of permanganate is formed at the end of 3 mins.' boiling, and when one-third of the total oxygen has evolved. The alkalinity or OH'-ion conc. of

the soln. is a critical factor in the case of copper, but is comparatively unimportant in the case of cobalt, though large conc. of alkali hinder permanganate formation. Moderate amounts of manganese salts can be completely oxidized to permanganate in the presence of copper, independently of the amount of manganese present. When cobalt is used, however, the proportion of permanganate formed decreases in a regular manner with increasing amounts of manganese. The form and the mode of action of the precipitates of cobalt and copper differ in several respects. That of cobalt is flocculent, finely divided, and difficult to filter, and promotes copious evolution of oxygen from the hypochlorite throughout the reaction. The copper precipitate, at first flocculent, soon passes into a dense black residue, easily separated, and becomes considerably less active as regards hypochlorite decomposition after the formation of the permanganate has taken place. The cobalt, when used in the form of the double sodium carbonate, cannot be completely separated from the soln. by boiling, as is the case with moderate quantities of copper. B. E. Dixon and J. L. White explain the main reaction as follows : the first effect of the hypochlorite is to form copper peroxide and hydrated manganese dioxide. The oxidation of manganese dioxide to permanganate, which can proceed in the presence of manganese alone, is greatly accelerated by the copper peroxide, which gives up its active oxygen, possibly through the intermediate formation of an unstable compound of copper and manganese, and is reconverted to the cupric form. At this stage much of the hypochlorite has been decomposed, and the hydroxyl-ion concentration, due to the alkali which is necessarily present in the hypochlorite soln., becomes an important factor. The excess of hydroxyl ions has an inhibitive effect on the formation of fresh copper peroxide, and the main reaction is arrested. If, however, the carbonate–bicarbonate mixture is used, (i) its buffer action renders the influence of the alkali negligible, and (ii) owing to the delayed precipitation of the copper, much of the earlier part of the reaction takes place in the liquid phase, and the oxidation of the manganese proceeds to completion. C. M. Tessié du Motay treated the cake of manganate from the furnace—$vide\ supra$, the extraction of manganese—with a conc. soln. of magnesium sulphate : $3K_2MnO_4 +2MgSO_4=2KMnO_4+MnO_2+2K_2SO_4+2MgO$. C. Huggenberg recommended boiling barium manganate with a soln. of potassium carbonate while carbon dioxide is passing through the soln. The potassium permanganate passes into soln., and the precipitate of hydrated manganese dioxide and barium carbonate is treated with steam and the product used for making more barium manganate. The manufacture of permanganate on an industrial scale was discussed by E. Schütz, J. C. Sticht, M. I. Belotzerkowsky, E. Desclabissac, R. B. Stringfield, E. Geay, and J. Bendix. O. Dieffenbach observed that alkali manganates can be made by the action of permanganates on manganese dioxide or other manganese oxides suspended in a hot, conc. alkaline soln. which is kept agitated. The permanganate is produced in the soln. itself as wanted by the electrolytic or chemical oxidation of the ready-formed manganate. Other oxidizing agents can be used to start the process. The process can be symbolized : $2KMnO_4+MnO_2+4KOH=3K_2MnO_4+2H_2O$, and $6K_2MnO_4+3H_2O+3O=6KMnO_4+6KOH$; or, if the two equations are summed : $MnO_2+KOH+1\frac{1}{2}O=KMnO_4+\frac{1}{2}H_2O$. The first of these three equations is reversible, but equilibrium is but slowly attained. O. Sackur and W. Taegener calculated from observations on the potential that the equilibrium constant for $[K_2MnO_4]^3K=[KMnO_4]^2[OH']^4$ is $K=1\cdot6\times10^{-4}$; and the equilibrium concentrations in equilibrium with a mol of $KMnO_4$ per litre—$vide\ supra$, manganates—are :

OH' (N)	0·1N-K$_2$MnO$_4$	0·01N-K$_2$MnO$_4$	0·001N-K$_2$MnO$_4$
1·0	0·0004	0·000013	0·0000004
0·1	0·04	0·0013	0·00004
0·01	4	0·13	0·004
0·00000001 (neutral)	4×10^{10}	$1\cdot3\times10^9$	4×10^7

The permanganate can be obtained by an electrolytic process—$vide\ supra$,

permanganic acid. Thus, H. N. Warren electrolyzed alkali-lye, using ferromanganese as anode and a graphite plate as cathode. R. Lorenz obtained a soln. of potassium permanganate by passing a current of 1·5 volts potential between an anode of commercial manganese or ferromanganese and a cathode of porous copper oxide dipping in a soln. of potash-lye. Ferric oxide collects as anode slime. Soln. of potassium manganate can be converted into permanganate by electrolytic oxidation, with or without a diaphragm. A. N. Campbell studied the electrolytic oxidation of manganous salts to permanganates. He found that with a soln. of 0·7767 grm. of manganese as sulphate and 191 grms. of sulphuric acid per litre, the optimum conditions are at 0° and a current density of 1·7 amp. per sq. dm., and that chlorides and nitrates should be absent. Evidence of the formation of the disulphate was also obtained. Electrolytic processes were described by K. Elbs, F. W. Skirrow, O. T. Christensen, Salzbergwerk neu Stassfurt, G. Rapin, G. J. A. Griner, R. E. Wilson and co-workers, C. O. Henke and O. W. Brown, J. Roudnick, P. Askenasy and S. Klonowsky, F. Weckbach, F. Krause, A. Manasse, K. Brand and J. E. Ramsbottom, G. Grube and H. Metzger, M. de K. Thompson, A. N. Campbell, L. de Putnoky, L. de Putnoky and B. de Bobest, A. J. Hale, H. C. Jenkins and H. Woolner, R. Lorenz, W. J. Müller, G. R. White, and F. Deissler—*vide supra*, manganese, and manganates. P. Askenasy and S. Klonowsky found that with iron electrodes, without diaphragm, a soln. of 80–90 grms. of potassium manganate per litre at 60°, a cathodic current density of about 0·8 amp. per sq. cm., and an anodic current density 6–8 times smaller, that cathodic reduction is not important, and that potassium permanganate soon crystallizes out. About 60 per cent. of the manganate is oxidized when the theoretical quantity of electricity for complete oxidation has passed through the soln. ; the loss of efficiency is due largely to the escape of free oxygen. About 75 per cent. of the manganate can be converted, and further oxidation is balanced by cathodic reduction. Platinum electrodes and a diaphragm give rather better yields, but the voltage must be doubled or tripled. More dilute or colder soln. decrease the yield. According to K. Brand and J. E. Ramsbottom, the yield of permanganate is increased by stirring the anodic liquor, and it decreases with an increase of the anodic current density. The yield is much greater with a nickel anode than with an iron anode, indicating that the oxygen primarily formed on the nickel oxidizes faster than when formed on iron.

Analyses of potassium permanganate were made by E. Mitscherlich, H. Aschoff, A. Gorgeu, and M. V. Machuca. The results agree with the empirical formula $KMnO_4$. The hypothesis of T. L. Phipson, and A. Terreil that the salt is either K_2MnO_7 or $KHMnO_4$ was contradicted by M. V. Machuca, C. M. Bradbury, and E. J. Maumené. F. M. Raoult showed that the formula $KHMnO_4$ cannot be right, because the salt contains no combined water. The subject was discussed by J. Personne, J. Personne and M. l'Hermite, E. Erlenmeyer and G. Lewinstein, C. M. Bradbury, G. Bredig, E. Franke, and J. M. Crofts. H. E. Armstrong and R. T. Colgate regarded the acid as a per-acid of the type $MnO_2.O.OH$; and R. T. Colgate represented it by the formula :

$$KO.O.Mn.O.O : O.O.Mn.O.OK$$
$$KO.O.Mn.\overset{..}{O}.O : \overset{..}{O}.\overset{..}{O}.Mn.O.OK$$
P. Niggli, and A. M. Taylor discussed the **electronic structure.** According to P. F. Chevillot and W. F. Edwards, potassium permanganate crystallizes in dark purple needles having at first a sweet taste, and afterwards a rough one. The salt is stable in air, and does not redden litmus or turmeric. According to G. Foster and G. Brude, the crystals of potassium permanganate prepared in the dark and in air free from carbon dioxide and organic matter are brown and have a bronze, metallic lustre. The finely-powdered crystals, however, show a dark violet colour. When exposed to subdued daylight and ordinary air, the surfaces of the crystals develop a violet colour in a few hours, and a steel-blue lustre after two days. This

change is confined to the surface layer, which acts as a protective layer to the remainder of the crystal. The change is particularly rapid in an atm. containing mineral acid. The crystals of potassium permanganate should be described as bipyramidal rhombs rather than as prisms. J. W. Retgers said that thin microscopic crystals appear red by transmitted light. E. Mitscherlich pointed out that the **crystals** are ismorphous with those of potassium perchlorate. W. Muthmann gave for the axial ratios of the rhombic bipyramids $a : b : c = 0.7972 : 1 : 1.2982$. The (001)- and (110)-**cleavages** are perfect. T. V. Barker gave for the topic axial parameters $\chi : \psi : \omega = 3.856 : 4.836 : 6.278$. The crystals are pleochroic. The crystals were examined by C. F. Rammelsberg, H. Mark and co-workers, and P. Groth. H. E. Buckley studied the habit of the crystals grown in different media. W. Basche found that the **X-radiogram** of potassium permanganate corresponded with a rhombic lattice having $a = 9.10$ A., $b = 5.69$ A., and $c = 7.40$ A., and 4 mols. per unit cell. The calculated axial ratios are $1.60 : 1 : 1.30$. R. C. L. Mooney gave for the rhombic crystals $a = 9.08$ A., $b = 5.72$ A., and $c = 7.41$ A., and each unit cell has four molecules. W. Büssem and K. Herrmann studied the subject.

The possibility of forming **isomorphous mixtures** with barium sulphate was discussed by W. Geilmann and E. Wünnenberg, E. Wilke-Dörfurt and R. Pfau, D. Balareff and co-workers, G. Wagner, V. Chlopin and B. Nikiton, and H. Grimm and G. Wagner. G. Wagner studied the X-radiograms of the mixed crystals; and E. Köstermann and co-workers, the solid soln. with potassium borofluoride, KBF_4. F. Zambonini discussed the isomorphism of potassium permanganate and fluoborate. C. M. Bradbury observed no isomorphous mixtures are formed with sodium or

Figs. 53 and 54.—Relations between the Composition of Solutions and Isomorphous Mixtures for the respective Systems : $KMnO_4$–$KClO_4$, and $KMnO_4$–$RbMnO_4$, at 7°.

silver permanganate, but the crystals are isomorphous with those of potassium perchlorate, and, added J. W. Retgers, with those of potassium periodate, KIO_4. E. Sommerfeld said that the isomorphous solid soln. of potassium permanganate and perchlorate are formed without a perceptible rise of temp. F. Rinne, and W. Muthmann and O. Kuntze found that a series of isomorphous mixtures is formed. Soln. containing C_1 and C_2 millimols respectively of potassium permanganate and perchlorate per litre at 7° furnish mixed crystals with the following mol. percentage proportion of the permanganate (Fig. 53) :

C_1	.	.	29.375	67.726	108.14	159.17	201.55	233.75	258.14
C_2	.	.	54.478	42.745	37.95	31.15	21.27	28.26	14.22
$KMnO_4$	.	.	2.838	9.778	19.276	40.120	84.469	94.372	96.48

Similar results were obtained with potassium and rubidium permanganates, with the same designations for the letters as before, but with C_2 standing for rubidium permanganate (Fig. 54) :

C_1	.	.	27.038	79.046	120.26	171.96	204.97	207.39	225.12
C_2	.	.	22.691	18.178	31.29	41.66	45.36	41.46	25.99
$KMnO_4$	.	.	3.498	13.746	34.293	74.973	99.406	99.363	99.324

A. Fock concluded that two series of isomorphous mixtures between potassium perchlorate and permanganate and potassium and rubidium permanganates are continuous, and, from an application of the partition-law, that the molecules of the

salts in question have twice as great a mol. wt. in the solid state as they have in soln. The isomorphous mixtures of potassium permanganate with rubidium permanganate and with potassium perchlorate were studied by G. Tammann and A. Sworykin. T. V. Barker found that the axial ratios of the isomorphous mixtures of potassium permanganate and perchlorate, $a : b : c—b$ unity—vary as follows :

$KMnO_4$	0·6	1·5	3·1	51·8	95·4 per cent.
a	0·7814	0·7817	0·7822	0·78975	0·7969
c	1·2807	1·2817	1·2815	1·2907	1·2985

G. Tammann and A. Sworykin discussed the protection of one salt by another in the case of a solid soln. of potassium permanganate and perchlorate in a soln. of perchlorate. H. E. Buckley studied the effect of permanganates on the crystallization of sodium chlorate.

H. Kopp found the **specific gravity** of potassium permanganate to be 2·709 to 2·710 ; and W. Muthmann, 2·7032. F. Flöttmann found that soln. sat. at 15°, 20°, and 25° had the respective sp. gr. 1·0342, 1·0391, and 1·0469. W. Muthmann gave 58·526 for the **molecular volume.** The subject was discussed by F. A. Henglein, and A. F. Hallimond. A. H. Schulze gave for the **specific volume** of aq. soln. :

	5°	10°	15°	20°	25°	30°
$0·1N\text{-}KMnO_4$	0·99996	1·00029	1·00095	1·00189	1·00308	1·00453
$0·01N\text{-}KMnO_4$	0·99991	1·00018	1·00078	1·00171	1·00248	1·00427

A. M. Patterson gave 1·035 for the sp. gr. of a sat. soln. at 15°. H. Sentis found that the **surface tension** of a 2·93 per cent. soln. at 15·4° is 73·84 dynes per cm., and the **specific cohesion**, $a^2 = 14·79$ per sq. mm. Z. Stary studied the effect of an electric field on the capillary rise. É. Ullmann, and I. D. Götz and G. P. Pamfil studied the velocity of **diffusion** of the salt ; and E. Ullmann found the diffusion coeff. to be $15·2 \times 10^{-6}$. N. P. Peskoff studied the diffusion of adsorbed permanganate from a ferric oxide hydrosol to a soln. of urea. He called the phenomenon *barophoresis*. P. Henry observed no evidence of diffusion with isomorphous crystals of potassium perchlorate and permanganate after being heated for several days. I. I. Saslawsky gave 2·71 for the sp. gr., and he calculated the contraction which occurs in forming the salt from its elements. J. N. Rakschit studied the contraction which occurs when the salt is dissolved in water. H. Kopp gave 0·179 for the **specific heat** of the solid. H. Aschoff observed that the crystals decrepitate when heated to 100° owing to included water. P. F. Chevillot and W. F. Edwards studied the **action of heat** and found that 10·8 per cent. of oxygen is given off at a temp. exceeding 200°, and a black mixture of potassium manganate and manganese dioxide remains. P. Thénard said that the reaction $2KMnO_4 = MnO_2 + K_2MnO_4 + O_2$ occurs at 240°, and when the residue is moistened with water, some oxygen is evolved. If the salt be more strongly heated, 15·3 per cent. of oxygen is given off, in accord with the equation : $2KMnO_4 = 3O + K_2O.2MnO_2$. P. Askenasy and A. Solberg found that G. Rousseau's statement that no manganate is formed at 240° is wrong even were the temp. 500°. P. Askenasy and A. Solberg showed that the evolution of oxygen from potassium permanganate begins to be appreciable at about 215°. When decomposition has commenced, oxygen continues to be evolved quite readily, even when the temp. is reduced to below 200°. The results agree with G. Rudorf's equation, but from the dissociation press. curve of manganese dioxide obtained by P. Askenasy and S. Klonowsky, Fig. 48, it is improbable that the residue contains free manganese dioxide. The dissociation press. of the residue was found to be 50 mm. at 505° ; 129 mm. at 560° ; 391 mm. at 594° ; and 400 mm. at 600°. From a comparison of the dissociation press. curves of manganese dioxide and potassium manganate, and of the residue resulting from the thermal decomposition of potassium permanganate, it is inferred that the decomposition should be represented by the equation : $10KMnO_4 = 2K_2MnO_3 + [3K_2MnO_4 + 5MnO_2] + 6O_2$, which agrees with the chlorine value of the residue. The reversibility of the reaction in which oxygen is evolved

by the heated residue suggests that the entire residue or the bracketed constituents represent a chemical compound. It may be, however, that the manganate and the dioxide form a solid soln. in which the manganite is dissolved. W. Hempel and C. Schubert, and C. Schubert said that the decomposition begins at 160°; and that the composition of the residue at 185° is $K_2Mn_2O_6$; at 570°, $K_2Mn_2O_5$; and at 1400°, $K_8Mn_8O_{14}$. E. Moles and M. Crespi found that the first sign of the decomposition of the dry salt occurs at 200°, and the pressures recorded below this temp. are due to water or to carbonates. Decomposition is complete at 240°, and the oxygen press. of the residue up to 485° correspond with those of manganese dioxide.
FIG. 55.—Dissociation Pressures of Potassium Permanganate.

Fig. 55 shows the dissociation curves of a sample of permanganate contaminated with carbon dioxide and water (dotted line), and of a sample of purified permanganate (continuous line). Potassium oxide is not a product of the decomposition, so that G. Rudorf's equation: $10KMnO_4 = 3K_2MnO_4 + 7MnO_2 + 2K_2O + 6O_2$ is not right; rather is a permanganite formed: $10KMnO_4 = 2K_2MnO_4 + 3K_2MnO_3 + 5MnO_2 + 13O$. E. Moles and M. Crespi concluded that the decomposition of the permanganates involves two reactions, which are autocatalytic, and they may be represented by the equation $dx/dt = (k_1 + k_3x/a)(a-x)$, or $(1/t) \log \{a/(a-x)\} + (1/t) \log (1/kx) = \text{Constant}$, where $k = k_2/k_1$. For potassium permanganate, $k = 0.881$. The two reactions involve a simple decomposition, and an autocatalytic decomposition which is negligible at first, but afterwards passes through a maximum value. The different velocity constants of decomposition for a number of permanganates are related with the heats of formation of the corresponding oxides. C. N. Hinshelwood and E. J. Bowen measured the rate of decomposition of potassium permanganate at 217° and 240°; of solid soln. of potassium permanganate and perchlorate at 239°; and of potassium permanganate and manganese dioxide at
FIG. 56.—The Thermal Decomposition of Crystals and Powdered Potassium Permanganate.
FIG. 57.—Effect of Admixed Oxides on the Thermal Decomposition of Potassium Permanganate.

220·5°. The decomposition appears to be confined to those molecules in the neighbourhood of the surface, and in the region where a progressive disintegration of the crystal structure takes place the change is strongly accelerated. Soln. in another solid causes a reduction in the rate of reaction. The results show that the molecules in the interior are under some kind of restraint; this may be connected with the fact that in the interior the molecules are bound by valency forces on all sides, or it may be referred to the internal pressure. S. Roginsky and E. Schulz also studied the thermal decomposition of potassium permanganate powdered and crystallized, and some results are illustrated by Fig. 56. There is a period of

induction and of autocatalysis for which the equation $dx/dt=kx(a-x)$ for many reactions in liquid system is not applicable. Surface again plays an important part. It was found that the decomposition is strongly accelerated by admixed NiO, Co_3O_4, MnO_2, Fe_2O_3, and CuO ; less vigorously by Mn_3O_4, Ag_2O, SnO_2, and PbO ; feebly by Sb_2O_5, Cr_2O_3, ZnO, Al_2O_3, CdO, and PbO_2 ; and very feebly or not at all by WO_3, MgO, TiO_2, HgO, CaO, U_3O_8, and SiO_2. This subject was also studied by K. Bädecker, F. Streintz, and G. Tammann and H. Bredemeier.

G. L. Voerman found the lowering of the **freezing-point** of aq. soln. containing 0·58, 1·01, 2·02, and 3·00 grms. of the salt in 100 grms. of water to be respectively ·—0·18°, —0·27°, —0·48°, and —0·58°. The last of the series is a eutectic mixture, so that the **eutectic temperature** is —0·58°. F. Guthrie found the eutectic temp. to be —0·57° with 2·82 per cent. of the salt. T. G. Bedford found the lowering of the f.p., $\delta\theta$, and the calculated degree of ionization, a, for soln. with n mols of the salt in 1000 grms. of soln. to be :

n	.	.	0·000615	0·00129	0·002	0·005	0·010	0·015
$\delta\theta$	.	.	—0·00225	—0·00481	—0·00732	—0·01800	—0·0357	—0·0534
a	.	.	—	—	0·970	0·935	0·920	0·915

G. Tammann found the lowering of the **vapour pressure** of water with 19·62, 56·06, and 111·13 grms. of potassium permanganate per 100 grms. of water to be 24·6 mm., 85·3 mm., and 197·1 mm. respectively. J. Thomsen calculated the **heat of formation** of the salt from its elements to be 194·825 Cals., and M. Berthelot, 200 Cals. ; A. Simon and F. Feher gave $2KMnO_4 \rightarrow 2K+2Mn+4O_2+389\cdot63$ Cals., and $(KOHaq., HMnO_4aq.)=13\cdot7$ Cals. ; while for the **heat of solution,** J. Thomsen gave —10·4 Cals. ; M. Berthelot, —10·2 Cals. ; and W. A. Roth and G. Becker, —10·62 Cals. per mol. E. Moles and M. Crespi gave 60·0 Cals. for the **heat of decomposition.**

F. Flöttmann found that even 1 per cent. soln. were too deeply coloured to enable the **index of refraction** to be determined by daylight or Na-light. Observations on the **absorption spectrum** of crystals of potassium permanganate were made by G. G. Stokes, K. Schnetzler, E. Wiedemann, and J. Conroy ; of aq. soln., by G. G. Stokes, V. R. von Kurelec, A. Hagenbach and R. Percy, A. M. Taylor, C. J. W. Grieveson, H. Gombos, H. Kautsky and O. Neitzke, B. K. Mukerji and co-workers, E. Wiedemann, J. Conroy, E. Brücke, E. Pflüger, A. Hantzsch and R. H. Clark, E. Viterbi, J. E. Purvis, J. Moir, W. Ostwald, K. Schnetzler, F. Vlès and A. Simchen, H. M. Vernon, E. Adinolfi, W. N. Hartley, T. R. Merton, etc.—*vide supra*, physical properties of manganese ; and of soln. in non-aqueous solvents by A. Hantzsch and R. H. Clark. According to the ionic theory of colour, the potassium ions are colourless, whilst the MnO_4'-ions are purple, and the ions behave with respect to colour independently of one another. Further, in completely ionized soln. with one coloured ion, the coloration is independent of the colourless ion, and in partially ionized soln. the coloration is the joint effect of the colour of the salt molecule and of the coloured ion. W. Ostwald found that the absorption spectra of thirteen permanganates are the same at great dilutions ; hence it was inferred that the absorption spectrum of a salt soln. is the sum of the separate spectra due to the neutral molecules, anions, and cations ; and if the soln. is very dilute, it is completely ionized, and the colour is entirely due to the ions. W. Ostwald's proof broke down when other investigators showed that the absorption spectra of conc. soln. of permanganates are also identical. A study of the absorption spectra of soln. of cobalt, copper, nickel, and other coloured salts led R. A. Houstoun to conclude that there is no spectroscopic evidence in favour of the theory of ionization ; rather is the evidence against that theory, unless it be supported by assumptions of hydrolysis, hydration, etc. W. W. Coblentz measured the ultra-red transmission spectrum of potassium permanganate. J. E. Purvis attributed the changes which occur on diluting soln. of the permanganates to the ionizing power of water acting slowly on the dissolved

permanganate so that the ionic condition $R^{\cdot}$ and MnO_4' breaks down. The MnO_4'-ion may be broken down into MnO_3''- and O''-ions or into manganese dioxide and oxygen. In dil. soln. the tension between the molecules of water surrounding the ions must be very considerable, and it may be so great as to destroy the MnO_4 condition, so that further changes take place, which become visible in changes of colour, in changes in the width of the bands, and in the liberation of oxygen ; and these changes would be accelerated by the vibrations of light. The intermediate stages of the changes might be represented by the narrowing of the bands 1, 2, and 3, and the widening of the bands 4 and 5, and these might correspond to changes of the MnO_4-ions into MnO_3 and O-ions. According to W. N. Hartley, in dil. soln. the permanganates are hydrolyzed and then decomposed into a colloidal soln. of manganic hydroxide, $MnO(OH)_2$, and free oxygen. This action occurs even when the soln. are made in darkness and preserved in the dark. The most striking change seen in the spectra is a greatly increased general absorption, that is, a shortening of the transmitted rays. With soln. preserved in darkness it is apparently proportional to the dilution, but the effect of sunlight greatly increases the decomposition. The narrowing of the bands $\lambda\lambda 546$ and 524, and the widening of those at $\lambda\lambda 504$, 486, are easily explained by the decomposition having diminished the quantity of the permanganate or permanganic acid, and therefore weakened the bands and increased the quantity of the hydroxide, $MnO(OH)_2$, in colloidal soln. ; this has greatly extended the general absorption until it in part overlies the more refrangible of the bands. The absorption bands of permanganates are not characterized by sharpness ; they have a hazy indistinctness, with no definite boundary lines such as are commonly seen in uranium, didymium, and erbium absorption spectra. Owing to these properties, if the light is not diminished in intensity but the permanganate is reduced in quantity, the intensity of the bands will be diminished, and this will cause a reduction in their width. If, however, the intensity of the transmitted light is diminished, the reverse effect will be seen in an increased width of the bands. The intensity of the light is not diminished so far down into the green as $\lambda 524$, but the colloidal soln. of the hydroxide, $MnO(OH)_2$, not only extends the complete absorption in the direction of the bands, but also enfeebles the transmitted rays by a partial absorption extending to $\lambda 504$. Hence, two of the bands in the less refrangible rays are narrower and two in the more refrangible rays are broader than in the unaltered soln. H. Becquerel showed that the greater the conc. of the soln. the greater the shift of the bands towards the red end of the spectrum. W. N. Hartley added that this means that the conc. soln. is mainly a soln. of the salt, and that dilution causes hydrolysis ; the shift of the edge of the band to a more refrangible group of rays is precisely what might be expected by the conversion of barium permanganate into hydrogen permanganate ; furthermore, we should expect the shift to be of greater extent in the case of the barium salt than in that of the zinc permanganate, as appears to be the case. T. R. Merton measured the absorption bands in soln. of various permanganates in different solvents—water, acetone, methyl acetate, acetic anhydride, pyridine, acetonitrile, methyl, ethyl, and amyl alcohols, and ethylene glycol—and also a solid soln. of potassium permanganate and perchlorate. In the last case the general character of the spectrum is the same as in liquid soln., but the bands are shifted towards the violet. The position of the bands in water is thus intermediate between the positions in the alcohols pyridine and acetone and the positions in the solid soln. The general nature of the absorption is due to the atomic grouping MnO_4, and it is influenced very little, if at all, by the nature of the cation or the extent of ionization, the position of the points of maximum absorption being determined by the nature of the medium in which the salt is dissolved. R. W. Wood measured the absorption spectrum of soln. in liquid ammonia. The **anomalous dispersion** of potassium permanganate was studied by A. Kundt, J. J. Soret, and O. T. Christensen.

According to E. K. Rideal and R. G. W. Norrish, when a soln. of potassium per-

manganate is illuminated by ultra-violet light, it undergoes a marked change of electrode potential, which slowly reverts to its original value when the light is extinguished. The change in light is attributed to an alteration in the hydrogen-ion concentration of the soln. brought about by photochemical decomposition of the potassium permanganate, thus : $2KMnO_4=K_2O.2MnO_2+3O$. The compound $K_2O.2MnO_2$ is precipitated and a red sol of manganese dioxide and potassium permanganite is formed. The decomposition is unimolecular over the range of conc. studied, and it is shown how the velocity constant can be calculated either from the changes of electrode potential during illumination or from the dark-recovery curve. The value of the equilibrium constant $K=0.00149$. A photochemical stationary state is produced in the soln. owing to removal of potassium hydroxide by combination with hydrated manganese dioxide. The rate of decomposition of potassium permanganate is increased by the addition of sulphuric acid to the soln. In such soln. the reaction, throughout almost the whole of its course, is of zero order, the constant velocity indicating continuous complete absorption of the photoactive radiation. This change in the type of decomposition is connected with the non-formation of colloid in the acid soln. Ammonium nitrate, uranyl nitrate, and potassium hypochlorite soln. afford photoactive effects similar to those observed with potassium permanganate. The ultra-violet absorption spectrum has a band between 3800 and 2700 with its head at 3130. The visible radiations of the mercury lamp are not appreciably effective in decomposing the soln. of potassium permanganate ; but the line 3128 A. is taken to be mainly responsible for the photochemical action. With this assumption, and taking the coeff. of absorption for green and yellow light to be the same as for ultra-violet light, it is probable that two quanta of energy are concerned in the photochemical decomposition of the permanganate ion. Mixtures of potassium permanganate and oxalic acid are more sensitive to ultra-violet than to ordinary light. D. N. Chakravarti and N. R. Dhar studied the fluorescence of soln. A. Kailan found the salt is decomposed by radium radiations, but O. Risse observed no photolysis on exposing to X-rays. K. Chamberlain, and G. L. Clark and L. W. Pickett found that the salt is reduced by exposure to X-rays, and this interferes with the measurement of the X-rays absorption. A. E. Lindh, D. Coster, and O. Stelling studied the X-ray spectrum. E. Montignie found that after exposure to ultra-violet light, potassium permanganate affects a photographic plate. W. Schneider studied the piezoelectric effect.

G. Bredig gave for the eq. **electrical conductivity,** λ mhos, of soln. containing a mol of the salt in v litres of water at 25° :

v	.	.	32	64	128	256	512	1024
λ	.	.	121·7	125·3	128·3	130·3	131·2	132·4

and at 0°, W. C. D. Whetham found for n mols of the salt in a litre of water:

n	.	.	0·020	0·010	0·005	0·001	0·0005	0
λ	.	.	70·6	72·2	73·5	75·1	75·5	75·9

Observations on the electrical conductivity, λ, and the degree of ionization, a, at temp. between 0° and 35°, made by L. G. Winston and H. C. Jones, are as follow :

v	.	8	32	128	512	1024	2048	4096
	0° .	59·34	63·75	66·76	66·46	64·65	63·72	62·64
λ	12·5°	80·17	87·13	91·38	91·14	89·05	86·61	87·94
	25° .	104·36	113·70	119·34	117·90	113·95	110·80	111·80
	35° .	124·74	136·05	142·42	141·49	137·09	133·02	133·97
	0° .	0·888	0·954	1·000	0·995	0·968	0·954	0·938
a	25° .	0·875	0·953	1·000	0·988	0·955	0·929	0·937
	35° .	0·876	0·955	1·000	0·994	0·963	0·934	0·941

Measurements were also reported by E. Bouty, H. C. Jones and co-workers, R. Lorenz and W. Michel, P. Walden, A. Ferguson and I. Vogel, and E. Legrand. A. Berthoud said that the supposed maximum in the mol. conductivity curve is due to experimental errors. A. A. Noyes and K. G. Falk calculated for the **degree**

of ionization, a, of soln. with 0·020, 0·010, and 0·005 mols per litre the respective values $a=0·913$, 0·921, and 0·938 from f.p. data ; and 0·930, 0·951, and 0·968 from conductivity data—*vide supra*. The subject was discussed by H. M. Vernon. W. Bein calculated 0·559 for the **transport number** of the anion at 25°—but the result is doubtful. The subject was studied by L. Engel and W. Pauli. R. Lorenz and W. Neu measured the velocity, V, and transport number, v, of the MnO_4'-ions at 18° and 25°, and reported the following data :

	0·25N-	0·0625N-	0·015625N-	0·0078125N-	0·001953125N-	0·0004878049N-
18° $\{V\times10^7$	433·1	485·2	513·3	523·6	537·6	541·0
$\{v$	41·9	46·82	49·54	50·53	51·88	52·52
25° $\{V\times10^7$	503·6	564·1	596·9	608·8	625·1	628·92
$\{v$	48·60	54·33	57·60	58·75	60·32	60·92

K. F. Ochs measured the potential of platinum in soln. of permanganate and sulphuric acid. O. Sackur and W. Taegener calculated from the e.m.f. of the cell $Pt : KMnO_4,K_2MnO_4 : KOH,HgO \mid Hg$, that the **oxidation potential** of potassium permanganate in alkaline soln. exceeds that of oxygen at one atm. press. and at room temp. The normal potential for the change $MnO_4' \rightleftharpoons MnO_4''+F$ is $E_H=0·61$ volt, and the equilibrium press. of the soln., containing manganate, permanganate, and OH'-ions of normal concentration, is nearly 6×10^{13} atm.—*vide supra*, manganic and permanganic acids. D. J. Brown and H. A. Liebhafsky calculated for the oxidation potential of the reaction $MnO_4'+8H^·+5e \rightleftharpoons Mn^{··} +4H_2O+1·446$ volts ; and D. J. Brown and R. F. Tefft obtained 1·586 volts for the potential of the manganese dioxide—permanganate electrode. S. Popoff and co-workers were unable to measure the potential of the permanganate—hydrogen —manganese dioxide electrode, for potassium permanganate soln. containing perchloric acid are unstable in the presence or absence of manganese dioxide. For the electrode potential of manganese dioxide in permanganate soln., *vide* manganese trioxide. F. Weigert studied the **electrolytic reduction** of soln. of potassium permanganate by a platinum cathode charged with hydrogen. At potentials smaller than that required to liberate hydrogen gas, the current passing is due to the reaction between hydrogen and the oxidizing agent in the soln. The velocity of this reaction is a function of the press. of the hydrogen and of the conc. of the oxidizing agent in the soln. in immediate contact with the cathode. If depolarization is so rapid that the depolariser at the cathode is used up, the current passing is fixed by the velocity with which the depolarizer can diffuse to the cathode. G. Baborovsky studied the electrolytic reduction of permanganate at a magnesium anode. In neutral and alkaline soln. MnO_4''-ions are primarily formed. G. Wenger and H. H. Alvarez concluded from their observations on the reduction of acidic soln. of potassium permanganate by an alternating current : (i) The reduction is strongest with rotating electrodes whatever may be their nature. (ii) Copper electrodes reduce the soln. the most rapidly, whilst aluminium in twice the time only effects a partial decomposition. (iii) In the experiment with the current the phenomenon is more pronounced at the beginning than at the end of the experiment. (iv) The reduction due to the sole action of the metal is, of course, almost negligible with platinum electrodes (non-oxidizable metal). A. W. Warrington described a two-liquid cell with potassium permanganate as the depolarizing agent ; G. P. Vincent also studied the depolarizing action of the permanganate.

E. Wedekind and C. Horst found the **magnetic susceptibility** of manganese compounds increases with the valency up to that of potassium permanganate. P. Pascal gave $25·5\times10^{-5}$ mass unit for the magnetic susceptibility of the salt ; E. Wedekind gave $0·18\times10^{-6}$. P. Collet calculated the at. magnetization of manganese, from the paramagnetism of solid potassium permanganate, to be $56·5\times10^{-6}$, and it is independent of the temp. between 15° and 150°. The paramagnetism is raised by impurities. The value for soln. of the salt is 62×10^{-6} and it is constant between 17° and 100°. The subject was studied by L. A. Welo and A. Baudisch,

G. Meslin, S. Freed and C. Kasper, and G. Quincke. T. Ishiwara, and K. Honda and T. Ishiwara gave for the effect of temp. on the magnetic susceptibility :

	$-170.4°$	$-93.5°$	$-34.1°$	$9°$	$94.5°$	$162.0°$
$\chi \times 10^6$.	0·179	0·170	0·176	0·175	0·175	0·184

According to P. F. Chevillot and W. F. Edwards, when the crystals are heated in **hydrogen,** they become red-hot, and diminish in bulk, at first rapidly, and then slowly, with the formation of a green mixture of potassium hydroxide and manganous oxide, in accord with the equation: $2KMnO_4+5H_2=2KOH +2MnO+4H_2O$. F. Duran studied the absorption of hydrogen by the solid. V. Meyer and A. Saam found that the absorption of hydrogen by a 5 per cent. soln. of potassium permanganate proceeds at a uniform speed when the liquid is agitated ; and F. Hein and W. Daniel added that the solubility of hydrogen in aq. soln. is greatly favoured if silver salts, *e.g.* the nitrate, be present. F. Jones found that a neutral aq. soln. of potassium permanganate is reduced by hydrogen : $2KMnO_4+4H_2=Mn_2O_3+2KOH+3H_2O$, especially when warmed ; the reduction in alkaline soln. is slow. W. Ipatieff and A. Kisseleff found that at 300° hydrogen under press. over 150 atm. reduces potassium permanganate soln. to form hausmannite, $Mn_3O_4.H_2O$. J. A. Wanklyn and W. J. Cooper found that if acidic, alkaline, or neutral soln. are allowed to stand in contact with hydrogen, the gas is absorbed and the soln. reduced. L. Delwaulle observed that in acidic soln., hydrogen precipitates manganese dioxide with the evolution of oxygen ; in neutral soln., colloidal manganese dioxide is formed, but no oxygen is evolved ; and in alkaline soln., potassium manganate is first formed, and ultimately manganese dioxide. V. Meyer and M. von Recklinghausen found that if an acidic soln. be shaken with hydrogen, some oxygen is given off as the soln. is reduced, but if the soln. is not acidified, reduction occurs without the evolution of oxygen. This evolution of oxygen soon reaches a limit, though if the soln. be allowed to stand quietly, the decomposition takes place continuously, and a far larger amount of oxygen is given off ; nevertheless, the action is not reversible. They represented the reaction :

$$\frac{H_2}{H_2}+\frac{0.0}{0.0}=2H_2O+O_2$$
H. Hirtz and V. Meyer concluded that the production of oxygen from acidic soln. cannot be attributed to the reducing action of the precipitated hydrated manganese dioxide on the permanganate. The oxygen evolved does not contain ozone, since that gas is produced only with conc. acid. F. Hein and W. Daniel found that whilst a soln. of pure silver nitrate reacts only slowly with hydrogen at ordinary temp., a soln. of potassium permanganate in the presence of hydrofluoric acid or silver nitrate quickly absorbs hydrogen. Thus, the number of c.c. of hydrogen absorbed by a sat. soln. of potassium permanganate, mixed with various substances are as follow :

	0 02N-HF	0·02N-AgF	0·02N-AgNO$_3$	0 06N-AgNO$_3$	0·16N-AgNO$_3$	0 02N-AgClO$_3$
H$_2$-absorbed .	12·7	85·2	100·0	30·0	80·0	30·0

The nitrates of copper, mercury, and lead have very little action in favouring the absorption of hydrogen by the permanganate. With a sat. soln. of silver permanganate 30 c.c. of hydrogen were absorbed.

H. N. Morse and co-workers showed that finely-divided manganese dioxide can reduce soln. of potassium permanganate with the liberation of oxygen : $2HMnO_4+nMnO_2=H_2O+(n+2)MnO_2+1\frac{1}{2}O_2$—*vide supra*, permanganic acid. The reaction was discussed by R. T. Colgate. H. Hirtz and V. Meyer thought that manganese dioxide cannot be the cause of the liberation of oxygen during the absorption of hydrogen by acidified soln., because no oxygen is evolved with neutral soln., although manganese dioxide is also present. H. N. Morse and C. L. Reese, however, thought that the liberation of oxygen by hydrogen is due to the pre-

cipitated manganese dioxide, and that the action is continuous, without the limit suggested by V. Meyer and M. von Recklinghausen.   H. N. Morse and C. L. Reese said that the oxygen is evolved more rapidly during the absorption of hydrogen than is subsequently the case when the precipitated manganese dioxide reacts with the permanganic acid.   The molecules of the manganese dioxide originally precipitated by a gaseous reducing agent are of greater simplicity and are capable of more rapid action than those produced by a solid like manganous sulphate. H. N. Morse and H. G. Byers concluded that with acidic soln. the liberation of oxygen is due to the reduction of the permanganic acid by the precipitated manganese dioxide, rendered active by the sulphuric acid which is present.   The fact that no oxygen is liberated in neutral soln. may be due to the potassium permanganate being more stable than permanganic acid, or to the precipitated manganese dioxide being saturated with alkali, or to both causes combined.   The falling off with the time of the reducing power of the manganese dioxide in acid soln. is explained by assuming the initial activity of the manganese dioxide molecules to be due to their simplicity ; as the molecules become more complex owing to polymerization, so do they lose their power of reduction.   It was noticed that whilst the oxide formed in acidified soln. is, in general (especially in the more conc. soln.), more active during the first 24 hrs. than that formed in neutral soln., the converse is true after 150 hrs.   In support of this, J. C. Olsen and F. S. White found that manganese dioxide precipitated from a sulphuric acid soln. of a permanganate persistently retains adsorbed sulphuric acid during the washing, whereas with nitric acid soln. the nitric acid can be easily removed by washing.   The reduction of permanganic acid by manganese dioxide is attributed to the weak basic properties of manganese dioxide, and its tendency to unite with sulphuric acid rather than with nitric or permanganic acid.   The amount of sulphuric acid retained by the precipitate is inversely proportional to the excess of oxygen in the precipitate, as adsorbed permanganic acid, over that required for manganese dioxide.   Consequently, manganese dioxide acts as a base and combines with sulphuric or permanganic acid.   The adsorbed permanganic acid readily decomposes, with the evolution of oxygen, forming a polymerized manganese dioxide, which is much less active than manganese dioxide itself.   V. Meyer and co-workers rejected the hypothesis that the oxygen is derived from hydrogen dioxide, but H. E. Armstrong and R. T. Colgate assume that hydrogen dioxide is a product of the oxidation, and they represent the reaction by the equation, with manganese dioxide as catalytic agent :

$$\frac{MnO_2 \, O.OH}{MnO_2 \, O.OH} + \frac{H\cdot OH}{H \, OH} + (MnO_2) = \frac{MnO_2}{MnO_2} + \frac{HO.OH}{HO.OH} + HO.OH + (MnO_2)$$
where 3 mols. of hydrogen dioxide would be formed and, in agreement with the equation of H. N. Morse and co-workers, produce $1\frac{1}{2}$ mols. of oxygen when decomposed catalytically by manganese dioxide.   G. Just and Y. Kauko observed that with neutral soln. of potassium permanganate of different concentrations, and with hydrogen mixed with varying proportions of nitrogen, the rate of reaction is proportional to the conc. of each of the reacting substances, and therefore that one mol. of hydrogen reacts primarily with one mol. of permanganate.   It follows that a quinquevalent, very unstable salt of manganese is formed as an intermediate product.   The manganese dioxide formed in the course of the reaction has no effect on the rate.   The speed of the reaction is approximately doubled by raising the temp. from 15° to 25°.   E. Wilke and H. Kuhn found the reaction not so simple as was assumed by G. Just and Y. Kauko, owing to the separation of manganese oxide.   The speed of oxidation is decreased in the presence of acids or alkalies, or by exposure to X-rays.   K. Volz discussed the oxidizing action of the permanganates.

A. Skrabal and J. Preiss found that in the spontaneous decomposition of soln. of potassium permanganate there is a period of induction, just as in the case of

permanganic acid (*q.v.*). The reduction of potassium permanganate soln. is a complex process involving a series of consecutive reactions between the products of the reduction, and between these products and the permanganate itself, and the decomposition of the permanganate resulting in the evolution of oxygen, a reaction influenced by catalytic effects of the products of the decomposition. A. Skrabal considered that the reduction in acidic soln. involves a *period of incubation*, during which the permanganate is reduced in accord with $Mn^{vii}=Mn^{ii}+O_2$; a *period of induction*, in which $Mn^{ii}+Mn^{vii}=Mn^{iii}$, and the change of the tervalent manganese by two side reactions: $Mn^{iii}=Mn^{ii}+Mn^{iv}$, and $Mn^{iii}=Mn^{ii}+O_2$; and there is the *terminal period*, when $Mn^{iv}=Mn^{ii}+O_2$. These reactions occur if no reducing agent is present, while in the presence of reducing agents one or more stages may be accelerated, and more permanganate may be consumed than is equivalent to the oxidation of the reducing agent. This subject has been discussed by A. V. Harcourt, A. V. Harcourt and W. Esson, R. Ehrenfeld, R. Luther, N. Schiloff, etc.—*vide supra*, permanganic acid, and manganese dioxide. The self-reduction of the permanganate is so very slow in feebly acidic and neutral soln. that they can be kept a long time when of a high degree of purity, and employed as volumetric soln. for analytical work. A. A. Maximoff studied its deoxidation in alkaline soln. F. Duran studied the absorption of **oxygen** by the solid.

E. Mitscherlich found that 100 parts of **water** at 15° dissolve 6·25 parts of the salt. Some observations on the solubility of the salt in water were reported by F. Guthrie, O. Sackur and W. Taegener, W. Herz and M. Knoch, and A. M. Patterson. W. Muthmann and O. Kuntze gave 4·184 grms. per 100 c.c. of sat. soln. at 7°. The following results are compiled from those of G. L. Voerman, E. C. Worden, and G. P. Baxter and co-workers for the percentage solubility, S:

	- 0·18°	− 0 58°	4°	10°	19·80°	29 80°	40°	50°	60°	75°
S .	0·58	2·91	3·15	4·01	5·96	8·28	10·78	14·40	18·03	24·44

F. Flöttmann gave for the solubility at 15°, 20°, and 25° respectively 0·327, 0·391, and 0·469 mols per litre, or 4·997, 5·946, and 7·079 per cent.

P. F. Chevillot and W. F. Edwards, and R. Luboldt stated that if the aq. soln. of potassium permanganate be free from reducing agents, it can be preserved unchanged; and similar remarks apply to the crystals of the salt, for they are permanent in air. H. N. Morse and co-workers said that permanganate soln. should not be filtered through paper, but rather through asbestos; such soln. exhibit a high degree of stability, whether kept in darkness or in diffused daylight; but soln. of a high degree of purity are decomposed in direct sunlight. R. W. Oddy and J. B. Cohen also found that the stability of soln. is not perceptibly affected by exposure to light, but after 14 days the titre of the soln. was slightly less; and J. C. Bell found that only a small reduction occurred after the soln. had been kept for some months. C. Meinecke and K. Schröder found that the titre remained constant for two months with soln. whose surface was covered by a layer of vaseline oil. R. Luboldt found that aq. soln. of the purified salt were not perceptibly decomposed after being boiled for half an hour. J. O. Halverson and O. Bergeim discussed the preparation of soln. which do not vary more than 0·1 per cent. per week. The subject was discussed by O. Hackl, G. Bruhns, I. M. Kolthoff and co-workers, and W. M. Gardner and B. North. P. A. Tscheishwily found that a soln. of potassium permanganate in distilled water alone suffered no reduction in eight months; a reduction occurred after each of the first eight filtrations through asbestos, after which reduction no longer occurred on filtration; a clear filtrate could not be obtained through glass-wool. The presence of various sulphates all caused a slow reduction of the permanganate; with chrome-alum the reduction is rapid. T. Warynsky and P. A. Tscheishwily found that the decomposition of $0·01M$-$KMnO_4$ with $\frac{1}{10}M$-H_2SO_4, in the presence of various salts used as catalysts, is accelerated in the dark, but is a retarded action in daylight. Also, in green and blue light most salts retarded the action, but in orange light a slight acceleration

was observed ; the retarding effect, therefore, probably depends on the actinic rays. A rise of temp. also affects the catalytic power of salts on the reaction ; it increases the activity of the sulphates of iron, chromium, and aluminium, but retards the action of cadmium sulphate. The activity of certain catalysts, such as ferric alum, increases with the concentration. According to E. Mitscherlich, an aq. soln. of potassium permanganate, acidified with sulphuric or nitric acid, slowly evolves bubbles of oxygen gas at 30°, but with a boiling soln. the decomposition is rapid; hydrated manganese dioxide is precipitated. A. Skrabal and J. Preiss found that in the spontaneous decomposition of soln. of potassium permanganate there is a period of incubation, just as in the case of permanganic acid (q.v.). J. Holluta found that $0 \cdot 004N$-KMnO$_4$ is not decomposed by long boiling, even on adding small quantities of manganese sulphate; more dil. soln., say $0 \cdot 002N$-KMnO$_4$, are slowly decomposed by boiling, possibly by the intermediate formation of KMnO$_3$, followed by the formation of K$_2$MnO$_4$ and MnO$_2$. The decomposition of permanganic acid, or acidified soln. of potassium permanganate, has been previously discussed. The decomposition of the permanganate in alkaline soln. was studied by R. H. Ferguson and co-workers.

TABLE 11.—THE SOLUBILITY OF POTASSIUM PERMANGANATE IN SOLUTIONS OF POTASSIUM HYDROXIDE.

Temp.	H$_2$O	N-KOH	2N-KOH	4N-KOH	6N-KOH	8N-KOH	10N-KOH

If a soln. of potassium permanganate and conc. **potassium hydroxide** be boiled, E. Mitscherlich, R. Luboldt, and H. Aschoff observed that the liquid becomes black, then green, and it develops oxygen, forming potassium manganate. The reaction was studied by A. A. Maximoff. C. F. Schönbein observed that an excess of potassium hydroxide gradually decolorizes a soln. of potassium permanganate and a hydrated manganic dioxide is precipitated which, when treated with an acid, separates iodine from potassium iodide. C. F. Mohr, P. Thénard, R. Böttger, and C. F. Rammelsberg found that a dil. soln. of alkali-lye prepared from the hydroxide which has been fused does not change the permanganate ; and P. F. Chevillot and W. F. Edwards found that the permanganate soln. is reduced by potassium hydroxide purified by alcohol—and therefore containing organic matter—and likewise by a sodium carbonate soln. which has been frequently filtered through paper. The reduction which occurs with ordinary alkali-lye was also attributed by G. Forchhammer, and H. Aschoff to the presence of organic matter ; by G. Forchhammer, to potassium sulphide ; and by E. Bohlig, to the presence of thiosulphate. Many substances rich in oxygen were found by P. Thénard to accelerate, by contact, the action of alkali-lye on hydrated manganese dioxide, but not so, added H. Aschoff. The action of this agent has been discussed in connection with permanganic acid, and with the action of hydrogen on potassium permanganate. According to E. Mitscherlich, if a conc. soln. of the crystals of potassium permanganate in dil. alkali-lye be evaporated in vacuo, the crystals are re-formed with only a slight loss by decomposition ; but a very dil.

soln. slowly becomes green at ordinary temp. and more rapidly if the temp. be raised. In order that the change to green manganate may be complete, the quantity of aq. soln. must be sufficient to absorb the oxygen liberated in the passage of permanganate to manganate. The green soln. is reddened by acids, with the separation of hydrated manganese dioxide. O. Sackur and W. Taegener measured the solubility of potassium permanganate, expressed in mols per litre, in soln. N-KOH to $10N$-KOH, and the results are given in Table II. P. F. Chevillot and W. F. Edwards found that the permanganate soln. is also turned green by a soln. of **sodium, barium, or strontium hydroxide.** The action of a soln. of **calcium hydroxide** is slight, owing to the great dilution of the liquid. It was suggested that complex salts are formed, because in the case with barium hydroxide no barium permanganate is precipitated although that salt is virtually insoluble in water. O. Sackur and W. Taegener found the solubility, S mols per litre of sat. soln., in soln. of **potassium carbonate** to be:

K_2CO_3		$0.1N$-	N-	$2N$-	$4N$-	$6N$-
	$0°$	0·1462	0·0629	0·0446	0·0270	0·0156
S	$25°$	0·4375	0·2589	—	0·0930	—
	$40°$	0·7380	0·5007	0·3519	—	—

and in soln. of **potassium chloride** to be :

KCl		$0.1N$-	$0.5N$-	N-	$2N$-
	$0°$	0·1395	0·0760	0·0532	0·0379
S	$25°$	0·4315	0·3060	0·2200	0·1432
	$40°$	0·7380	0·5840	0·4400	0·2880

W. Herz and F. Hiebenthal gave for the solubility, S, of potassium permanganate in n-normal soln. of various salts :

LiCl	n	0	0·51	0·87	2·56	3·81	4·56	
	S	2·25	2·18	2·09	1·51	1·16	0·95	
NaCl	n	0·59	0·96	2·26	3·35	4·22	5·15	
	S	2·32	2·29	2·13	1·86	1·73	1·53	
NH$_4$Cl	n	0·59	0·95	2·69	3·78	4·57	5·45	
	S	1·94	1·75	1·05	0·86	0·78	0·72	
MgCl$_2$	n	0·96	1·92	4·62	6·42	7·64	8·10	9·52
	S	2·01	1·78	0·96	0·64	0·48	0·40	0·16
CaCl$_2$	n	1·70	4·96	6·80	8·10			
	S	2·00	1·20	0·91	0·80

	S	2·27	1·94	1·64	1·54	1·36		
KCl	n	0·36	0·61	1·65	2·32	2·89	4·06	
	S	1·56	1·30	0·74	0·58	0·51	0·40	

for LiCl, $S=2.250-0.285n$; for NaCl, $S=2.422-0.173n$; for NH$_4$Cl, $S=2.50$ $-0.446n$, and $S=1.370-0.120n$; for MgCl$_2$, $S=2.250-0.279n$, and $S=1.700$ $-0.161n$; for CaCl$_2$, $S=2.318-0.188n$; and for SrCl$_2$, $S=2.250-0.157n$. H. M. Trimble found the percentage solubilities, S, in soln. of **potassium sulphate** and of **sodium sulphate,** at $25°$, are as follow. The soln. sat. with respect to both salts are marked with an asterisk.

K$_2$SO$_4$.	0·00	0·80	1·98	5·47	7·79	9·26*	10·75

K$_2$MnO$_4$	7·10	7·33	—	7·75	7·27	6·25	5·91	0·00
Sp. gr.	1·0454	1·0554	—	1·1180	—	1·2363	—	1·2071

The solubility of potassium permanganate in soln. of potassium sulphate decreases with increasing conc. of the sulphate. In soln. of sodium sulphate the solubility increases to a maximum with increasing conc. of sodium sulphate. The maximum solubility lies at about 6 per cent. of sodium sulphate, after which there is a slow decrease in solubility to a minimum in soln. which contain the maximum amount

of sodium sulphate soluble in the presence of permanganate crystals. For the lower conc. of each sulphate, potassium sulphate acts powerfully in decreasing the solubility of potassium permanganate in soln. of sodium sulphate, whilst sodium sulphate increases its solubility in soln. of potassium sulphate to a much smaller degree.

According to C. F. Schönbein, **hydrogen dioxide** decomposes a soln. of potassium permanganate, with the separation of hydrated manganese dioxide. In neutral soln. C. Weltzien represented the reaction : $2KMnO_4 + 2H_2O_2 = 2KOH + (Mn_2O_3 + 2O_2) + 3H_2O$. L. Swiontkowsky obtained a similar result for feebly acidic soln. F. Wöhler and A. Geuther and others also found that the manganese dioxide (*q.v.*) also reacts with the hydrogen dioxide in acidic soln. H. Aschoff represented the initial and final stages of the reaction by $2KMnO_4 + 3H_2SO_4 + 5H_2O_2 = 2MnSO_4 + K_2SO_4 + 8H_2O + 5O_2$. B. C. Brodie said that three consecutive reactions are involved : the permanganate in alkaline soln. reacts with the alkali dioxide, forming a manganate ; the manganate then passes to hydrated manganese dioxide ; and the precipitate, in the presence of an acid, gives off oxygen and forms a manganous salt ; B. C. Brodie, and E. Schöne added that the reaction does not start at once, but once it is started it proceeds very rapidly. L. Maquenne, and R. Engel suggested that a trace of a manganous salt must first be formed, and it is this which reduces the permanganate to a manganic salt, and the latter is reduced by the hydrogen dioxide to a manganous salt, and so the cycle begins anew. The permanganate forms the manganic salt in the presence of sulphuric acid only very slowly. P. H. Segnitz found the reaction is accelerated by a soln. of a manganous salt. According to M. Martinon, if a soln. of potassium permanganate be added to an acidic soln. of hydrogen dioxide, the reaction is symbolized : $2KMnO_4 + 5H_2O_2 + 6HCl = 2MnCl_2 + 2KCl + 8H_2O + 5O_2$, whereas if the acidic soln. of hydrogen dioxide is added to the permanganate, a precipitate of hydrated manganese dioxide is formed, and the reaction is symbolized : $6KMnO_4 + 9H_2O_2 + 6HCl = 6KCl + 2H_4Mn_3O_8 + 9O_2 + 8H_2O$. This reaction also varies in character with the rate at which the hydrogen dioxide is added to the soln. If a neutral or alkaline soln. of hydrogen dioxide is added to the soln. of the permanganate, the reaction progresses in accord with $KMnO_4 + 2H_2O_2 = KOH + Mn(OH)_3 + 2O_2$. If the soln. of permanganate is very dilute and very alkaline, a small quantity of manganate is momentarily formed when hydrogen dioxide is slowly added—*vide* 4. 31, 33. A. Gorgeu also found when hydrogen dioxide is added to a soln. of permanganate, the quantity of dioxide decomposed varies from 3 to 11 eq. per eq. of permanganate ; but when the permanganate is added to the hydrogen dioxide, there is no limit to the amount of hydrogen dioxide which is decomposed. When hydrogen dioxide is added to an alkali permanganate, the precipitate retains a considerable quantity of alkali, and a larger proportion of dioxide is required for complete decolorization. A combination of manganese dioxide and the alkali seems to be formed, and reacts readily with the hydrogen dioxide. At first a brown soln. is formed, which very readily decomposes, and which probably contains potassium permanganite. In the presence of a large excess of alkali the brown liquid is not formed. The permanganate is first converted into the green manganate, and the latter is then decolorized. J. Zawidzky gave for the speed of the reaction : $dx/dt = k(1-x)x^{-\frac{1}{4}}$, where $k = 0.119$ and 0.379 respectively at $-16°$ and $15°$. A. A. Maximoff observed that if hydrogen dioxide or the peroxide of the alkali metal be added in excess to a soln. of the hydroxide and permanganate of sodium or potassium, no manganate is formed, but a vigorous reaction, resulting in the production of manganese dioxide, takes place. The quantities of hydrogen dioxide necessary for complete deoxidation to manganate and to manganese dioxide respectively are in agreement with the theory that the reaction takes place in two consecutive stages, given for potassium permanganate by the equations $2KMnO_4 + H_2O_2 + 2KOH = 2K_2MnO_4 + 2H_2O + O_2$, and $2K_2MnO_4 + 2H_2O_2 = 4KOH + 2MnO_2 + 2O_2$. These equations hold only when the potassium hydroxide conc. is greater

than about $0.5N$. If it is less than about $0.05N$, hydrated manganese dioxide is formed simultaneously with potassium manganate ; a rise of temp. has a similar effect. It is considered that the formation of a peroxide of an alkali metal is a necessary intermediate stage of the reaction. Observations on the reaction were also made by W. Ramsay, P. Thénard, M. Berthelot, A. Bach, R. T. Colgate, N. A. Tananaeff, A. Clever, and A. von Bayer and V. Villiger.

V. Thomas and P. Dupuis observed that liquid **chlorine** at its b.p. has no action on the solid permanganate ; G. Gore, that liquid **hydrogen chloride** attacks the solid permanganate, making it swell up, but does not dissolve it ; J. W. Thomas, that the dry gas vigorously attacks the crystals, with the development of heat, forming chlorine, water, potassium chloride, and manganous and manganic chlorides. K. Fredenhagen studied the action of **hydrofluoric acid.** O. Ohmann, and C. Graebe found that with **hydrochloric acid** chlorine is evolved. The reaction between potassium permanganate and hydrochloric acid was studied by R. F. Weinland and P. Dinkelacker. J. Wagner thought that the reaction is catalyzed by ferric chloride, but J. Brown did not find it so. The reaction is a convenient one for making chlorine for laboratory purposes on a small scale. The reaction is represented : $2KMnO_4 + 16HCl = 2KCl + 2MnCl_2 + 8H_2O + 5Cl_2$. F. P. Venable and D. H. Jackson represent it as a two-stage reaction : $2KMnO_4 + 8HCl = 2KCl + 2MnO_2 + 4H_2O + 3Cl_2$, followed by $MnO_2 + 4HCl = MnCl_2 + 2H_2O + Cl_2$ if enough acid be present. There is a reaction with $0.00154N$-**hydrobromic acid,** but no reaction occurs with less than $0.02N$-HCl. D. Balareff and G. Kandilaroff observed that owing to adsorption barium sulphate reduces the speed of oxidation of hydrogen chloride in dil. soln. by permanganate. R. Lang observed that an excess of potassium permanganate in $5N$-sulphuric acid oxidizes **iodine, hydriodic acid,** and **iodic acid** to periodic acid. The reaction is hindered by chlorides. C. W. Hempel, M. Gröger, and W. Lindner observed that **potassium chloride and bromide** are not attacked by a boiling neutral soln. of the permanganate. M. A. Rozenberg found that an increase in the acidity of the soln. changes the reaction with a bromide from a multimolecular to a monomolecular one : $MnO_4' + 5Br' + 8H^{\cdot} = Mn^{\cdot\cdot} + 5Br + 4H_2O$. L. P. de St. Gilles found that iodine is converted into iodic acid ; and M. Gröger, that **potassium iodide** is converted into iodate—these reactions proceed best in the presence of alkali carbonate or hydrocarbonate : $KI + 2KMnO_4 + H_2O = KIO_3 + 2KOH + 2MnO_2$. M. Bobtelsky and D. Kaplan discussed the action of various salts on the reaction. The reaction is utilized in the volumetric titration of the iodides, and it was discussed by C. W. Hempel, R. Espenchied, C. Weltzien, F. L. Hahn and G. Weiler, C. F. Mohr, E. Sonstadt, S. Popoff and A. H. Kunz, E. Brücke, M. Gröger, and A. Longi and L. Bonavia. E. Müller and H. Möllering observed that in sulphuric acid soln. the reaction is complicated by the formation of an iodate, and in hydrochloric acid soln. by the formation of iodine chloride. According to E. Fürst, **chlorine dioxide** forms potassium chlorate and manganese dioxide : $KMnO_4 + 3ClO_2 + H_2O = MnO_2 + KClO_3 + 2HClO_3$. G. R. Levi and D. Ghiron found that permanganates oxidize **chlorites** to chlorates, in accord with $3ClO_2' + 2MnO_4' + H_2O = 3ClO_3' + 2MnO_2 + 2OH'$.

P. F. Chevillot and W. F. Edwards found that when solid potassium permanganate is triturated with **sulphur** partial detonation may occur, but when heated the mixture may explode. J. B. Senderens said that sulphur reduces a soln. of the permanganate at ordinary temp : $2KMnO_4 + S + 2H_2O = 2(MnO_2.H_2O) + K_2SO_4$; and J. W. Slater observed that when the mixture is boiled a sulphate is formed, while M. J. Fordos and A. Gélis added that some non-oxidized sulphur is carried along by the steam, and some dithionate may be formed. S. Cloez and E. Guignet observed that a boiling, sat. soln. of permanganate slowly oxidizes the sulphur in green powder to sulphuric acid. P. F. Chevillot and W. F. Edwards found that an excess of **hydrogen sulphide** decolorizes a soln. of the permanganate, forming potassium sulphate and precipitating pale red manganous sulphide, and

also, according to H. Rose, some sulphur. C. F. Schlagdenhauffen observed that if the permanganate be added to an aq. soln. of hydrogen sulphide, a brown precipitate is formed which rapidly turns white, and with more permanganate a clear soln. and black precipitate are formed. According to H. B. Dunnicliff and S. D. Nijhawan, when a slow current of hydrogen sulphide is passed through a 1 per cent. soln. of potassium permanganate, the purple soln. becomes brown and a white deposit of sulphur appears round the delivery tube. After a short time a greyish-brown solid separates without appreciable rise in temp.; this slowly changes, first to a yellow mixture of hydrated manganese dioxide, manganese sulphide, and sulphur, and finally to a pink precipitate of manganese sulphide containing much sulphur, the temp. rising rather more than 10°. Other observations by H. B. Dunnicliff and S. D. Nijhawan are indicated in connection with hydrogen sulphide. A. Peter, L. P. de St. Gilles, and S. Cloez and E. Guignet found that **alkali sulphides** are oxidized to sulphates, and C. F. Schlagdenhauffen added that the reaction proceeds faster if a dil. soln. of the sulphide be added to the warm soln. of permanganate. M. Bobtelsky and D. Kaplan discussed the action of various salts on the reaction. H. Pinsl represented the reaction: $8KMnO_4 + 3Na_2S + 4H_2O = 8KOH + 8MnO_2 + 3Na_2SO_4$. According to M. Hönig and E. Zatzek, **alkali polysulphides** with cold soln. form trithionate and sulphur, while with warm soln. alkali sulphate and sulphuric acid are formed. The addition to a permanganate soln. of **ammonium hydrosulphide** results in the precipitation of a rose-coloured manganese sulphide; the reaction with sulphides was studied by L. P. de St. Gilles, A. Longi and L. Bonavia, J. W. Slater, W. R. E. Hodgkinson and J. Young, J. Mijers, J. B. Senderens, M. J. Fordos and A. Gélis, T. S. Dymond and F. Hughes, C. Luckow, M. Hönig and E. Zatzek, R. Böttger, and C. F. Schlagenhauffen. L. P. de St. Gilles observed that most **metal sulphides** are oxidized by the permanganate; and C. F. Schlagdenhauffen added that the reaction is complete with the sulphides of copper, calcium, zinc, bismuth, manganese, iron, and nickel, and incomplete with those of mercury, tin (ic), lead, arsenic, and antimony. P. F. Chevillot and W. F. Edwards, and H. Buignet found that **sulphur dioxide** or **sulphurous acid** acts on a soln. of permanganate, forming alkali and manganous sulphates; M. J. Fordos and A. Gélis added that some dithionate may be formed, and that in the presence of alkali carbonates the conversion of the sulphite to sulphate is almost complete. W. R. E. Hodgkinson and J. Young studied the reduction of the permanganate by dry sulphur dioxide. H. P. Cady and R. Taft found the salt to be insoluble in liquid sulphur dioxide. F. Durau studied the absorption of sulphur dioxide by the solid. M. Hönig and E. Zatzek found that **alkali sulphites** are completely oxidized to sulphate at ordinary temp., whether in neutral or alkaline soln. The quantity of permanganate consumed in the reaction is smaller the more dilute the soln. of the permanganate; and the composition of the precipitate varies with the concentration of the soln. of permanganate. This subject was discussed by M. Gröger, and W. S. Hendrixson. R. Böttger found that alkali sulphite turns permanganate soln. green, and J. Mijers added that with very dil. soln., say one part of sulphite in 100,000 parts of soln., the red permanganate soln. is coloured indigo-blue; the red coloration returns after about 24 hrs. When sulphurous acid is titrated with potassium permanganate under conditions where the escape of sulphur dioxide or oxidation by air is excluded, about 88 per cent. of the theoretical amount of permanganate is consumed as required by the equation: $5H_2SO_3 + 2KMnO_4 = 2KHSO_4 + 2MnSO_4 + H_2SO_4 + 3H_2O$. T. S. Dymond and F. Hughes trace this to the formation of dithionic acid. If the reaction be $17H_2SO_3 + 6KMnO_4 = 2K_2S_2O_6 + K_2SO_4 + 6MnSO_4 + 6H_2SO_4 + 11H_2O$, then 88·2 per cent. of the oxygen required to convert all the sulphurous into sulphuric acid will be required. The temp., acidity, and conc. of the soln. make no difference to the result. S. Cloez and E. Guignet found that **sodium thiosulphate** is oxidized to the sulphate; and, added L. P. de St. Gilles, the reaction is almost complete in the presence of alkali carbonates. M. Hönig and E. Zatzek observed that in the

cold the reduction of the permanganate is complete, and only independent of the concentration of the permanganate in alkaline soln.; one part of $Na_2S_2O_3.5H_2O$ consumes 1·6366 parts of $KMnO_4$, and the precipitate approximates in composition to $KH_3Mn_3O_8$; on the other hand, M. Gläser observed that with hot, conc., neutral soln. the reaction is complete; one part of $Na_2S_2O_3.5H_2O$ consumes 1·6621 parts of $KMnO_4$, and the precipitate corresponds with $KH_3Mn_4O_{10}$; A. Alander found that some tetrathionate may be formed. M. Gröger discussed the reaction. J. Mijers found that one part of sodium thiosulphate in 200,000 parts of soln. will colour a red soln. of potassium permanganate indigo-blue, but the red colour is restored when the soln. is allowed to stand for 24 hrs. M. Bobtelsky and D. Kaplan discussed the action of various salts on the reaction. The reaction was studied by S. Popoff and J. L. Whitman, S. Popoff and F. L. Chambers, T. Milobendzky, K. Schröder, W. C. Vosburgh, J. M. Hendel, R. S. McBride, W. C. Bray and G. M. McKay, and W. C. Bray and H. E. Miller. According to H. Schjerning, a mixture of sodium sulphide and thiosulphate when boiled with the permanganate soln. for 15 mins. gives a cinnamon-brown precipitate of $Mn_3O_4.nH_2O$; but with cold soln. a precipitate of hydrated manganese dioxide, $MnO_2.nH_2O$, is formed. L. P. de St. Gilles found that **alkali dithionates** are not affected by a soln. of potassium permanganate, while **alkali trithionates** are incompletely oxidized, slowly in the cold, rapidly when heated. According to P. F. Chevillot and W. F. Edwards, the crystals of permanganate dissolve in **sulphuric acid** without effervescence, forming an olive-green soln.; the decomposition of the salt in soln. takes place very slowly. If water be progressively added to the olive-green soln., the colour changes in succession to light green, orange-yellow, and scarlet. Sulphuric acid, with dilutions up to a sp. gr. 1·60, forms a red soln. from which oxygen is evolved—in a few hours with conc. acid, and in a few months with dil. acid; the liquid is thus decolorized and brown hydrated manganese oxide precipitated. As indicated above, E. Mitscherlich observed that bubbles of gas are given off slowly from a soln. of the permanganate and sulphuric acid at 30°, but rapidly when boiled; hydrated manganese dioxide is precipitated. A. Bach found that **permonosulphuric acid** is quantitatively reduced to sulphuric acid. According to A. von Bayer and V. Villiger, a sulphuric acid soln. of **persulphuric acid** and potassium permanganate is a very powerful oxidizing agent, and it is at once decolorized by benzene and by adipic and phthalic acids. B. Brauner, and J. F. Norris and H. Fay observed that **tellurous acid** is oxidized by the permanganate to telluric acid, without precipitating manganese oxide.

According to J. A. Wanklyn and W. J. Cooper, **nitrogen** is not oxidized by permanganate soln. at 100°. G. Gore, E. C. Franklin and C. A. Kraus, and H. Moissan observed that potassium permanganate is very soluble in liquid **ammonia.** P. F. Chevillot and W. F. Edwards found that ammonia is decomposed by a soln. of potassium permanganate, and nitrogen is given off. H. Rose, and S. Hoogewerff and W. A. van Dorp said that the reaction is slow with dil. soln., even when heated on a water-bath, but, added L. P. de St. Gilles, it is greatly accelerated if formic acid be present. S. Cloez and E. Guignet observed that some alkali nitrite is formed in cold soln., and this with an excess of permanganate or in hot soln. forms the alkali nitrate. H. Tamm noticed that some ammonium nitrite may be formed; and F. Jones represented the reaction: $8KMnO_4 + 8NH_3 = 4Mn_2O_3 + KNO_2 + KNO_3 + 6KOH + 9H_2O + 3N_2$. The reaction was also studied by F. Wöhler, and J. A. Wanklyn and A. Gamgee. According to H. Rose, **ammonium salts** are not oxidized by the permanganate. W. Meyeringh found that **hydroxylamine salts** in the cold react with the permanganate with the evolution of nitrogen and nitric oxide, and when heated, nitric acid is formed. L. J. Simon represented the reaction with the nitrate: $2KMnO_4 + 5(NH_2OH.HNO_3) = 2Mn(NO_3)_2 + 2KNO_2 + 2N_2O + 10H_2O$; and with arsenate or phosphate: $12KMnO_4 + 16\{(NH_2OH)_3 . H_3PO_4)\} = 4Mn_3(PO_4)_2 + 6KH_2PO_4 + 2K_2HPO_4 + 2KNO_2 + 20N_2 + 3N_2O + 89H_2O$. T. Curtius and F. Schrader observed that **hydrazine salts** reduce permanganate to

the manganous state, and if an excess be added, a brown oxide is deposited.   The oxidation of hydrazine sulphate was also studied by W. Herz, and N. A. Orloff. U. Roberto and F. Roncali, and K. Weisbrod represented the reaction: $4KMnO_4 +6H_2SO_4=2K_2SO_4+4MnSO_4+6H_2O+5O_2$;   and $5O_2+5(N_2H_4.H_2SO_4)=10H_2O +5H_2SO_4+5N_2$.   J. Petersen represented the reaction: $17N_2H_4+13O=13H_2O +14NH_3+10N_2$.   This is also in agreement with L. Medri's results.   J. A. Wanklyn and W. J. Cooper observed that **nitrous oxide** is not altered by the permanganate soln. at 100°; and P. F. Chevillot and W. F. Edwards, that **nitric oxide** precipitates hydrated manganese dioxide and forms potassium nitrate.   J. A. Wanklyn and A. Gamgee found that nitric oxide is rapidly absorbed and oxidized by a cold soln. of permanganate, and the action is vigorous at 100°.   B. C. Dutt and co-workers represented the reaction: $KMnO_4+NO=KNO_3+MnO_2$, with no intermediate formation of nitrous acid.   L. P. de St. Gilles, G. Lunge, S. Feldhaus, and H. N. Morse and A. F. Linn also observed that in acidic soln. nitric oxide, and **nitrogen peroxide** are oxidized to nitric acid or nitrates— some nitrite may be formed.   S. Feldhaus, and W. Kubel found that **nitrites** are oxidized to nitrates, but L. P. de St. Gilles said that alkaline soln. of a nitrite is not oxidized by the permanganate soln.   M. Bobtelsky and D. Kaplan studied the action of various salts on the reaction with sodium nitrite. P. F. Chevillot and W. F. Edwards, and E. Mitscherlich observed that the behaviour of **nitric acid** on the permanganate resembles that of sulphuric acid.   According to P. F. Chevillot and W. F. Edwards, crystals of potassium permanganate detonate vigorously when triturated with **phosphorus;** the reaction is more violent if assisted by heat.   J. W. Slater said that phosphorus forms potassium phosphate when treated with the permanganate soln. at ordinary temp., and with a boiling soln. some phosphite is formed.   F. Jones observed that **phosphine** is oxidized to a mixture of phosphite and phosphate ; P. F. Chevillot and W. F. Edwards, that **phosphides** are oxidized to phosphates ; L. P. de St. Gilles, that **hypophosphites** in alkaline soln. are not completely oxidized to phosphates ; O. Kühling, that **phosphorous acid,** and **phosphites** are oxidized to phosphates ; and J. W. Smith utilized the reaction for the detection of the lower oxides in phosphorus pentoxide. J. W. Slater found that **hypophosphates** are converted by permanganate to phosphates.   P. F. Chevillot and W. F. Edwards found that **phosphoric acid,** of sp. gr. 1·80, dissolves potassium permanganate to form a green soln.   When **arsenic** is triturated with the solid salt, the mixture detonates.   J. W. Slater, and W. Foster observed that powdered arsenic is quickly oxidized by a soln. of potassium permanganate ; F. Jones, that **arsine** reacts in accord with : $2KMnO_4+AsH_3=Mn_2O_3 +K_2HAsO_4+H_2O$: P. F. Chevillot and W. F. Edwards, that **arsenic trioxide** colours the soln. brown or brownish-yellow, and if the conc. of the soln. be great enough, the liquid is decolorized, and a brown precipitate is formed—L. P. de St. Gilles, J. Holluta, R. Lang, O. Cantoni, F. Feigl and F. Wiener, A. Bose, W. T. Hall and C. E. Carlson, E. H. Swift and C. H. Gregory, M. Geloso, A. Bussy, C. Reichard, A. Guyard, G. Kessler, R. Lang, W. G. Vannoy, T. Oryng, and M. Travers added that the oxidation of arsenic trioxide is complete.   M. Bobtelsky and D. Kaplan studied the action of various salts on the reaction.   G. Bonnet found that **potassium arsenite** precipitates a brown manganese oxide ; and D. R. Hale discussed the induced reaction between potassium permanganate, sodium arsenite, and ferrous sulphate.   C. F. Schlagenhauffen found that **arsenic trisulphide** is incompletely oxidized by potassium permanganate—*vide supra*.   According to P. F. Chevillot and W. F. Edwards, and W. Foster, when **antimony** and solid potassium permanganate are triturated together, the metal inflames.   J. W. Slater found that powdered antimony is converted into potassium antimonate by a cold or boiling soln. of potassium permanganate ; F. Jones obtained the same product by the action of **stibine ;** and A. Reynoso, G. Kessler, and A. Guyard, by the action of **potassium antimonite.**   A. Bussy, C. Reichard, A. Guyard, and G. Kessler found that **antimony trioxide** is oxidized ;   W. Pugh studied the reduction to the tervalent

stage by antimonious salts in the presence of fluorides. C. F. Schlagenhauffen found that **antimony trisulphide** is incompletely oxidized by a boiling soln. of potassium permanganate, while **bismuth trisulphide** is completely oxidized under similar conditions. B. W. Gerland, and C. Friedheim found that **hypovanadates** are oxidized to vanadates. F. E. Brown and J. E. Snyder observed that **vanadium oxytrichloride,** hot or cold, has no action on potassium permanganate.

H. Zocher and H. Kautsky found that there is a faint green luminescence when potassium permanganate oxidizes oxydisilin, rhodamine, and other organic dyes. H. Moissan found that **boron** reduces a cold soln. of potassium permanganate. P. C. Ray and K. K. Chatterji studied the ternary system: potassium permanganate, **potassium fluoborate,** and water at 25°, and observed that **potassium fluoborato-permanganate,** $KBF_4.6KMnO_4$, is formed. H. Moissan and S. Smiles showed that **silicon,** prepared by sparking silene, reduces the cold soln. slowly and the hot soln. rapidly; while **silane** behaves in a similar manner. L. Kahlenberg and W. J. Trautmann observed that when a mixture of powdered silicon and permanganate is heated over the bunsen burner, an explosion occurs. F. Pisani found that **titanous salts** are oxidized to titanic salts. According to P. F. Chevillot and W. F. Edwards, a mixture of **carbon** with solid potassium permanganate does not take fire when triturated in a mortar, but when heated the mixture burns like tinder. T. Oryng, and A. Wassermann found that potassium permanganate is readily adsorbed from aq. soln. by animal charcoal. There is first a period of rapid adsorption, followed by a slow period during which the permanganate is reduced. Acids accelerate the rate of removal of permanganate from aq. soln., and the effect increases with the conc. of the acid. S. Clocz and E. Guignet found that a boiling soln. of the permanganate slowly oxidizes the carbon in gunpowder to carbon dioxide. According to V. Meyer and M. von Recklinghausen, H. N. Morse and H. G. Byers, V. Meyer and E. Saam, and H. Hirtz and V. Meyer, the reducing action of **carbon monoxide** on soln. of potassium permanganate resembles that with hydrogen (*q.v.*); and G. Just and Y. Kauko, that in neutral soln. of potassium permanganate the rate of reaction is proportional to the conc. of the carbon monoxide. It was found necessary, in order to get effective mixing of the gas and soln., to rotate the reaction vessels 5000 times per minute. The conc. variations were brought about by mixing the carbon monoxide with nitrogen. The reaction in the first place occurs between one mol. of carbon monoxide and one mol. of potassium permanganate, with the probable formation of an unstable quinquevalent manganese derivative. The influence of temp. was found to be such that an increase of 10° doubled the velocity of reaction. F. Durau studied the absorption of carbon monoxide and of **carbon dioxide** by the solid. The bleaching of potassium permanganate soln. by **percarbonates** is due to a reaction which is symbolized: $5K_2C_2O_6 +8H_2SO_4+2KMnO_4=2MnSO_4+6K_2SO_4+8H_2O+10CO_2+5O_2$, and accordingly the strength of potassium percarbonate as an oxidizing agent can be determined by titration of the sulphuric acid soln. with potassium permanganate. S. Clocz and E. Guignet, and E. Donath and H. Ditz stated that **carbon disulphide** is oxidized completely to carbon dioxide and sulphuric acid by alkaline soln. of permanganate, but E. Obach showed that if the disulphide is purified, it does not act on the solid salt, or on its neutral or acidic soln. The action with the ordinary disulphide is attributed to the presence of hydrogen sulphide, which is oxidized by the permanganate. E. Allary purified carbon disulphide by treating it with a soln. of the permanganate.

Organic substances can be oxidized by potassium permanganate, and in some cases all the carbonaceous matter can be burnt to carbon dioxide and estimated as such. The wet combustion process of determining carbon was discussed by R. Warrington and W. A. Peake, C. F. Cross and E. J. Bevan, A. H. Elliott, R. Phelps, R. Finkener, R. E. and W. M. Rogers, C. Brunner, E. Ullgren, L. U. de Nardo, H. Heidenhain, H. von Jüptner, F. A. Cairns, etc. According to E. Donath and H. Ditz, oxidations with acidic permanganate soln. are less energetic than

those with alkaline soln. An acidified, conc. soln. of permanganate, at a high temp., usually furnishes carbon dioxide and water, but in alkaline soln. oxalic acid is usually the final product. T. Macalpine found that hydrated manganese dioxide is formed when an alkaline soln. of permanganate is treated with **acetylene ;** and M. Berthelot, that the acetylene is oxidized to oxalic and formic acids and carbon dioxide. A. Donath and H. Ditz doubt if formic acid is produced. P. Truchot added that **ethylene** is oxidized by a neutral soln. of permanganate to formic acid and carbon dioxide ; C. Fromerz also found that ethylene is oxidized to carbon dioxide and water by an acidic soln. of permanganate, and, according to A. Steopoe, colloidal manganic hydroxide is formed. N. K. Adam and G. Jessop studied the action on compounds with ethylenic bonds. P. Truchot observed that a neutral soln. oxidizes **propylene** to formic and acetic acids. M. Berthelot found that **allylene** is oxidized by permanganate to oxalic acid, etc.; and F. and O. Zeidler, that propylene and other **olefines** also furnish oxalic acid. The subject was discussed by H. S. Davis. D. A. Howes and A. W. Nash studied the action of permanganates on the hydrocarbons ; and F. Durau, the absorption of **methane, ethane,** and **propane** byt he solid—F. Durau and V. Schnatz measured the heats of adsorption. M. Berthelot found that the **paraffin hydrocarbons** are attacked with difficulty by acidic or alkaline soln. of permanganate ; while with an acidic soln. **benzene** is oxidized to oxalic acid and possibly propionic acid ; **toluene,** to benzoic acid and another product ; **xylene,** slowly to toluic and terephthalic acids ; and **styrene,** to benzoic acid and carbon dioxide ; while C. Fromherz, and M. Berthelot found that **turpentine** is slowly converted into carbon dioxide and water. E. Donath and H. Ditz found that propylene, **iso-butylene,** and **amylene** yield oxalic acid. The reaction with benzene was studied by T. H. Norton, and S. Cloez and E. Guignet. E. Donath and H. Ditz observed that there is no perceptible action, but **dimethylbenzene** is readily oxidized, although toluene is not attacked. L. A. Bigelow studied the oxidizing action of permanganate on the side-chains. S. Cloez and E. Guignet found that a neutral soln. of the permanganate oxidizes **methyl alcohol** to formic acid and carbon dioxide ; S. Cloez and E. Guignet, P. F. Chevillot and W. F. Edwards, W. L. Evans and J. E. Day, H. Tamm, and T. Morawsky and J. Stingl, **ethyl alcohol** to potassium acetate, and from alkaline soln. E. T. Chapman and M. H. Smith, and E. Donath and H. Ditz obtained traces of oxalic acid. S. S. Bhatnagar and co-workers found that the reduction of permanganate by **chloral hydrate** is accelerated by a magnetic field. T. Morawsky and J. Stingl oxidized **glycerol** to carbon dioxide and water. W. L. Evans and co-workers studied the oxidation of **ethylene and propylene glycols ; glycolaldehyde, glyoxal, glycollic acid, and glyoxylic acid.** B. V. Tronoff and L. S. Nikonova studied the oxidation of the **amines** by permanganate ; and A. Buzagh, and R. Benedikt and R. Zsigmondy, the rate of reaction with chloral hydrate. B. V. Tronoff and co-workers studied the velocity of the oxidation of alcohol by potassium permanganate. The oxidation of alcohol and **ether** was observed by E. T. Chapman and W. Thorp, and F. Jones ; the various stages in the process, by M. Gröger ; and the catalytic effect of platinum-black, by C. F. Schönbein. B. V. Tronoff and co-workers studied the velocity of oxidation of ether. G. B. Frankforter and R. M. West, and J. Holluta and co-workers studied the reduction by **formaldehyde.** W. Eidmann, and A. Naumann found that **acetone** dissolves in a soln. of potassium permanganate. W. Herz and M. Knoch found the solubility of permanganate in aq. soln. with p per cent. acetone, expressed in S millimols—$\frac{1}{5}KMnO_4$—per 100 c.c. of soln., to be :

p .	0	10	20	40	60	70	80	90	100
S .	148·5	162·7	177·3	257·3	316·8	328·0	312·0	227·0	67·6

L. P. de St. Gilles found that oxidation of acetone does not occur with a boiling alkaline soln. of permanganate, but M. Berthelot said that it is oxidized very slowly to carbon dioxide and water. The reaction was studied by E. J. Witzemann.

E. von Cochenhausen represented the reaction: $6(CH_3.CO.CH_3)+21O_2$ $=6(CO_2H)_2.2H_2O+6CO_2$. The reaction was studied by M. Gröger. E. Donath and H. Ditz said that some oxalic acid is formed. E. S. Prschevalsky examined the action of permanganate on the phenylated fatty acids. According to L. P. de St. Gilles, in the presence of sodium carbonate a soln. of potassium permanganate oxidizes **formic acid** to carbon dioxide and water, and the alkaline soln. acts slowly when cold, rapidly when boiled. E. T. Chapman and W. Thorp said that in the presence of sulphuric acid the action is slow in the cold; L. P. de St. Gilles said that the acidic soln. does not oxidize formic acid. The mechanism of the oxidation of formic acid was discussed by N. Schiloff, J. Holluta and co-workers, W. H. Hatcher and C. R. West, and A. Skrabal and J. Preiss. An alkaline soln. of potassium permanganate was found by L. P. de St. Gilles slowly to oxidize **acetic acid.** L. Gmelin said that an acidic soln. of potassium permanganate oxidizes acetic acid very slowly, while E. Monier, O. Unverdorben, H. Rose, and E. T. Chapman and W. Thorp said that oxidation does not occur. W. Lossen represented the reaction with **sodium acetate** in alkaline soln.: $NaC_2H_3O_2+2KMnO_4=2MnO_2+(CO_2K)_2$ $+NaOH+H_2O$. A. Naumann found that potassium permanganate is soluble in **ethyl acetate,** and sparingly soluble in **methyl acetate.** B. V. Tronoff and co-workers studied the velocity of oxidation of esters. E. T. Chapman and W. Thorp also observed that **propionic acid** is not oxidized by an acidic soln. of the permanganate. E. Donath and H. Ditz observed that oxalic acid is formed in the oxidation of **butyric acid,** and also of **succinic acid.** L. P. de St. Gilles observed that in the presence of an excess of potassium carbonate, **oxalic acid** is not oxidized by potassium permanganate; M. Berthelot said that with a boiling soln. the oxidation to carbon dioxide and water proceeds slowly; T. Morawsky and J. Stingl, that in neutral soln. **potassium oxalate** is oxidized completely; and E. Fleischer represented the reaction between oxalic acid and a neutral soln. of the permanganate by: $8H_2C_2O_4+2KMnO_4=2MnC_2O_4+K_2C_2O_4+10CO_2+8H_2O$; and C. W. Hempel represented the reaction in the presence of sulphuric acid at 35° to 40° by: $2HMnO_4+5H_2C_2O_4+2H_2SO_4=2MnSO_4+10CO_2+8H_2O$. The mechanism of the reaction was discussed by A. V. Harcourt, A. V. Harcourt and W. Esson, A. Skrabal, R. Ehrenfeld, R. Luther, N. Schiloff, J. C. Witt, R. C. Banerji and N. R. Dhar, N. R. Dhar, R. P. Sanyal and N. R. Dhar, R. M. Purkayostha and N. R. Dhar, B. K. Mukerji and N. R. Dhar, A. Boutaric, G. N. Ridley, G. Scheff, M. A. Rozenberg, D. A. MacInnes, C. del Fresno, and M. Gröger. A. K. Bhattacharji and N. R. Dhar, and E. Shpolsky studied the effect of ultra-red radiations on the reaction.

The reaction between potassium permanganate and oxalic acid, $H_2C_2O_4$, in the presence of sulphuric acid, is slow at first, but progresses more quickly as time goes on, and finally proceeds with a fairly uniform velocity. It is also found that the speed of the reaction is accelerated by the presence of manganese sulphate, and if manganese sulphate be added to the mixture there is no initial acceleration. Hence it is inferred (i) that in the early stages of the reaction manganic sulphate is formed *very slowly,* in accord with: $2KMnO_4+4H_2SO_4+4H_2C_2O_4=K_2SO_4+Mn_2(SO_4)_3$ $+8H_2O+8CO_2$, and possibly, $2KMnO_4+8MnSO_4+8H_2SO_4=5Mn_2(SO_4)_3+8H_2O$ $+K_2SO_4$, and that this reaction proceeds more and more rapidly as the manganese sulphate accumulates in the system—period of induction or period of acceleration. (ii) That the manganese sulphate unites with the oxalic acid, forming a double compound supposed to be $Mn_2(SO_4)_3.H_2C_2O_4$. This reaction is supposed to proceed *too rapidly* for measurement. (iii) The double compound decomposes into manganese sulphate, carbon dioxide, and water by a reaction: $Mn_2(SO_4)_3.H_2C_2O_4\rightarrow2MnSO_4$ $+H_2SO_4+2CO_2$, which can be readily measured. The last two assumptions are invented to explain how the reaction in a soln. containing the eq. of $KMnO_4+7MnSO_4$ $+54H_2C_2O_4$ in mols., made up to 160 litres with water at 14°, proceeds as if it were unimolecular. Part of the soln. is removed from time to time by means of a pipette, treated with potassium iodide and sulphuric acid, and the separated

iodine determined by titration with a standard soln. of sodium thiosulphate. Let x denote the amount of potassium permanganate decomposed in the soln., at the time t, and expressed in terms of the number of c.c. of thiosulphate soln. required to decolorize the iodine in the soln. withdrawn by the pipette ; then $a-x$ will represent the amount of undecomposed permanganate present in the soln. Obviously when $t=0$, $x=0$, and if $k=(1/t)\log\{a/(a-x)\}$:

t	0	12	25	36	46	54 minutes
$a-x$	53·10	37·00	24·93	27·75	13·10	10·25 c.c. " thio "
k	—	0·0131	0·0131	0·0132	0·0132	0·0132

Allowing for the errors of experiment, the numbers in the last line indicate that a unimolecular reaction was measured ; the assumption that the molecule of the complex salt is $Mn_2(SO_4)_3.2H_2C_2O_4$ is a guess. The inference that the unknown molecule is formed too rapidly for measurement is made because the speed at which it is formed does not interfere with the measurement of the rate at which it decomposes, as evidenced by the numbers in the above table. The inference that the manganic sulphate is formed during the early stages of the reaction between oxalic acid and potassium permanganate is based on the slow rate at which the colour of the permanganate disappears during the early stages of the titration of oxalic acid with potassium permanganate, as contrasted with the rate at which the decolorization occurs in the later stages, or when manganese sulphate is purposely added to the soln. Velocity measurements of the reaction show the same thing, for instance, with the mixture $KMnO_4+54H_2C_2O_4$ made up with water acidulated with $10H_2SO_4$ to 160 litres (14°) ; $k=(1/t)\log\{a/(a-x)\}$:

t	0	2	5	13	16	31	41	59 mins.
$a-x$	68·05	67·72	65·80	14·36	11·30	8·77	7·00	4·72 c.c. " thio "
k	—	0·001	0·003	0·052	0·049	0·029	0·024	0·020

The gradual increase in the speed of the reaction up to a maximum corresponds with the inference that in the early stages of the reaction something is accumulating

in the system in steadily increasing quantities. The decline in the velocity constant after the maximum is reached does not agree with a unimolecular reaction. This means that there is not an indefinitely large supply of manganese sulphate available, as was the case when a large excess of this salt was purposely added to the system, and the amount of the decomposing salt decreases faster than corresponds with what would be the case with a unimolecular change ; this is because the source of supply is exhausting as the reaction progresses.

FIG. 58.—The Speed of the Reduction of Potassium Permanganate by Oxalic Acid.

The progress of the two reactions under consideration is well illustrated by Fig. 58, showing the amount of substance transformed in each reaction per unit time.

M. Bobtelsky and D. Kaplan measured the speed of decolorization of a small amount of potassium permanganate by a known excess of oxalic and sulphuric acids in the presence of various salts. The alkali chlorides exert a stronger accelerating influence than the nitrates or sulphates. The order of decreasing acceleration with the sulphates is $Li>Mg>NH_4>Na>K$. Ammonium nitrate exerts a marked acceleration, sodium nitrate is ineffective, and potassium nitrate retards the action. The action of the chlorides is the most sensitive towards changes of temp., and the action in increasing magnitude is $NH_4Cl<KCl<BaCl_2<SrCl_2<CaCl_2<MgCl_2<AlCl_3$. The nitrates are feebly sensitive towards temp. changes ; and the sulphates are partly feeble and partly moderate. Salts which are sensitive towards changes of temp. are also sensitive to changes of concentration, except in the case of ammonium nitrate, which is sensitive to changes of concentration, but only feebly so with respect to temp. The order of decreasing conc. sensitive-

ness is $AlCl_3 > CdSO_4 > MgCl_2 > ZnCl_2 > ZnSO_4 > KCl > NH_4Cl > NH_4NO_3 > NaCl > (NH_4)_2HPO_4$; the salts with a feeble action are $Li_2SO_4 > MgSO_4 > K_2SO_4 > (NH_4)_2SO_4 > Na_2SO_4 > KNO_3 > NaNO_3 > CaCl_2 > SrCl_2 > BaCl_2$. According to K. Schröder, some of the oxides formed in the reduction of potassium permanganate may be reoxidized by atm. oxygen. E. Müller and H. Kogert studied the electrometric titration of oxalic acid with potassium permanganate. C. Fromherz said that an acidic soln. of potassium permanganate oxidizes **tartaric acid** to formic acid, carbon dioxide, and water : $C_4H_6O_6 + 3O = 2H_2CO_2 + 2CO_2 + H_2O$. E. Donath and H. Ditz observed the formation of some oxalic acid. The reaction was also studied by E. T. Chapman and W. Thorp, A. N. Dey and N. R. Dhar, A. K. Bhattacharji and N. R. Dhar, W. G. Vannoy, and E. Monier ; with soln. sat. with potassium hydroxide H. Rose observed that tartaric acid forms a green soln. with potassium permanganate ; and with a neutral soln. E. Fleischer found that manganous tartrate is formed, and L. P. de St. Gilles reduced the acid to carbon dioxide and water. E. Monier observed that the action with acid permanganate is very slow. S. S. Bhatnagar and co-workers found that the reaction is accelerated in a magnetic field. H. Rose found that **racemic acid** behaves like tartaric acid in the presence of an alkaline soln. of the permanganate. A. K. Bhattacharji and N. R. Dhar, and B. K. Mukerji and N. R. Dhar studied this photochemical reaction. E. Donath and H. Ditz observed that with **lactic acid** some oxalic acid is formed. A. K. Bhattacharji and N. R. Dhar studied the action of light and of ultra-red radiations on the reduction. A. N. Dey and N. R. Dhar, V. Subrahmanyan, and T. E. Friedemann and co-workers, studied the reaction. L. P. de St. Gilles showed that in acidic soln. **malic acid** is oxidized to carbon dioxide and water ; E. Monier found the reaction very slow. W. H. Hatcher and C. R. West found that formic acid occurs as an intermediate product in the oxidation of malic, maleic, oxalacetic, fumaric, malonic, tartaric, lactic, and glycollic acids and glycol. L. P. de St. Gilles observed that at 80° **citric acid** is oxidized to acetone, carbon dioxide, and water by an acidic soln. of permanganate ; A. N. Dey and N. R. Dhar, A. K. Bhattacharji and N. R. Dhar, and E. Monier also studied this reaction. C. Fromherz found that an acidic soln. of permanganate is reduced to a brown hydrated manganese oxide by **stearic acid** and **oleic acid**. E. Monier observed that a neutral and an acidic soln. of permanganate easily oxidize **tannin, gallic acid,** and **pyrogallic acid.** R. Böttger found that when tannin or gallic acid is triturated dry with potassium permanganate, the mixture inflames. P. Kubelka and E. Sövegjarto, and B. V. Tronoff and A. A. Grigorieva studied the oxidation of salts of **benzoic acid** and of other **organic acids** by permanganate ; E. M. Stoddart, **cinnamic acid ;** T. B. Douglas, **sodium thiophenolate ;** and B. V. Tronoff and A. A. Lukanin, the effect of neutral salts on the velocity of oxidation of organic substances by permanganate. S. Cloez and E. Guignet found that a neutral soln. of permanganate oxidizes **urea** with difficulty ; while J. A. Wanklyn and A. Gamgee found that with a boiling alkaline soln. urea is oxidized, yielding 22 per cent. of its nitrogen as ammonia, and in a sealed tube at 160° to 220° very little ammonia is formed and free nitrogen is produced. E. Monier found that the oxidation is very slow in acidic soln. A. Claus found that an alkaline soln. of permanganate oxidizes **uric acid** to carbon dioxide and allantoin. P. F. Chevillot and W. F. Edwards oxidized **sugar** by alkali permanganate, and E. Monier, and F. Jones found the action very slow in alkaline soln.; and S. L. Ridgway, the action on glucose in acidic soln. E. Donath observed that some oxalic acid is formed by the action of cane-sugar, grape-sugar, lactose, and dextrose. E. J. Witzemann studied the oxidation of dextrose ; C. W. R. Powell, sucrose ; S. S. Nametkin, unsaturated organic compounds ; F. Ullmann and J. B. Uzbachian, derivatives of benzoic acid ; J. Hetper, sugars, phenols, hydroxyacids, and alcohols. Various other **organic substances** have been oxidized—*e.g.* with alkaline soln. of permanganates C. F. Mohr oxidized *starch*, and P. F. Chevillot and W. F. Edwards, *gum* and *paper* ; and with acidic soln. C. Fromherz oxidized

gum, paper, and *wood-fibre*; G. Fester and G. Brude, paper and other organic substances; S. G. Simpson, filter-paper; and E. Monier oxidized *gum, dextrine*, and *fats*; and C. Fromherz oxidized camphor, resin, glue, and olive oil. P. F. Chevillot and W. F. Edwards found that a mixture of *lycopodium* and solid potassium permanganate takes fire when treated with sulphuric acid. D. Vorländer and co-workers found that **acyl derivatives** are oxidized readily in acidic soln., but not so easily in alkaline soln. A. W. Hofmann, I. Guareschi, and S. Cloez and E. Guignet discussed the oxidation of **organic sulphur compounds**, and E. Donath and H. Ditz found thiophene is readily attacked by a 2 per cent. alkaline soln. of permanganate. The **alkaloids** are oxidized by acidic soln. of permanganates— thus, C. Fromherz oxidized morphine; E. Monier, quinine, and caffeine; G. Kerner, quinine; E. Caventou and E. Willm, Z. H. Skraup, and O. Hesse, cinchonine; and Z. H. Skraup, cinchonidine. D. Vorländer and co-workers found that **amines** are oxidized by acidic and alkaline soln. of permanganates. J. A. Wanklyn and A. Gamgee oxidized **aniline.** Other **organic nitrogen compounds** were oxidized by acidic soln.—*e.g.* C. Fromherz oxidized *egg-albumin, fibrin*, and the red colouring matter of blood; and D. Vitali, *animal tissue*. A. Naumann found that potassium permanganate is soluble in **benzonitrile.** R. P. Bell, and L. S. Kassel and N. K. Schaffer studied the velocity of the reaction at the liquid-liquid interface between a soln. of **benzo-o-toluidide** in benzene and an aq. soln. of potassium permanganate. According to S. Cloez and E. Guignet, **cyanogen** is oxidized by cold neutral soln. of potassium permanganate to form potassium nitrate, and similarly with **hydrocyanic acid,** which L. P. de St. Gilles oxidized to cyanic acid in alkaline soln., but he did not oxidize the hydrocyanic acid in acidic soln. K. Fredenhagen found the electrical conductivity, λ, in hydrocyanic acid to be for a mol of the salt in v litres :

| v . . | 5·534 | 8·890 | 23·40 | 104·5 | 195·0 | 1329 |
| λ . . | 142·1 | 214·1 | 263·5 | 310·5 | 340·2 | 511·0 |

L. Kahlenberg and H. Schlundt gave for soln. of a mol of salt in 5·5, 23·4, 104·5, and 1329 litres of liquid hydrogen cyanide the values λ=142, 264, and 311 respectively. L. P. de St. Gilles, and T. Morawsky and J. Stingl oxidized **thiocyanic acid** to cyanic and sulphuric acids in alkaline soln., and with acidic soln. E. A. Hadow, E. Erlenmeyer, and L. P. de St. Gilles oxidized thiocyanic acid to hydrocyanic acid and potassium sulphate, and similarly with **thiocyanates** in alkaline soln. M. Bobtelsky and D. Kaplan studied the action of various salts on the reaction. C. F. Schönbein, and R. C. Campbell oxidized **potassium ferrocyanide** to ferricyanide in acidic soln., and S. Cloez and E. Guignet in alkaline soln., but **potassium ferricyanide** was not changed. S. Cloez and E. Guignet found that with cold alkaline soln. **sodium nitroprusside** furnishes potassium nitrate. F. C. Calvert observed no special antiseptic properties on fungoid growths.

W. Foster found that all the common metals—*e.g.* zinc, and magnesium—reduce acidulated soln. of potassium permanganate, but dil. neutral soln. are reduced as well, even by finely divided gold, platinum, and tungsten. W. B. Giles observed that **copper** does not attack soln. of potassium permanganate, but F. Fischer, and M. C. Schuyten found that a dil. sulphuric acid soln. is readily reduced by copper. C. Friedheim, V. Meyer and M. von Recklinghausen, and W. Foster found that **silver, gold, and platinum** also do so. W. Crookes observed that hot soln. of potassium permanganate attack **magnesium** very slowly; and L. L. de Koninck found that potassium permanganate is not attacked by purified **zinc,** even in the presence of sulphuric acid, but it is attacked in the presence of ferrous salts or nitric acid. W. B. Giles also observed that zinc exerts no appreciable action on the soln. during 2 months' exposure. C. Boulanger observed the action of zinc on manganese salts. P. F. Chevillot and W. F. Edwards, W. B. Giles, D. Borar, and W. Foster found that **mercury** decolorizes a soln. of the permanganate, and is at the same time oxidized, forming, according to W. B. Giles,

mercurous oxide in the cold, and mercuric oxide when boiling. A. Gawalowsky observed that in the presence of mercury a soln. of potassium permanganate gradually turns deep bluish-violet, and if potassium hydroxide be present, some potassium manganate is formed, and if only a small proportion of the alkali-lye be present, a potassium mercury manganate and a black deposit of a mercurous manganate are formed. According to A. S. Russell and D. C. Evans, all metals more electropositive than mercury, except cobalt, go rapidly into soln. as sulphates, without the accompaniment of mercury, when their amalgams are shaken with a soln. of potassium permanganate in dil. sulphuric acid. W. Crookes found that a soln. of permanganate is attacked by **aluminium** very slowly when hot, while **thallium** attacks the soln. in the cold. V. Shuleikin and X. Solovova measured the radiation of heat in the thermite reaction with aluminium. C. Boulanger observed the action of aluminium on manganese salts. W. Foster noted that the soln. is reduced by **tungsten**. M. A. Parker and H. P. Armes found that in the reduction of an acidic soln. of potassium permanganate by **iron** there is a definite relationship between the extent of the reduction and the strength of the field.

D. Nishida and K. Hirabayashi found the oxidation of **cuprous oxide** by potassium permanganate in $3N$- to $5N$-H_2SO_4, at room temp., is quantitative: $2KMnO_4+14H_2SO_4+5Cu_2O=10CuSO_4+13H_2O+2MnSO_4+2KHSO_4$. M. Bobtelsky and D. Kaplan studied the effect of various salts on the reaction between potassium permanganate and **silver nitrate**. D. Balareff and co-workers discussed the adsorption of permanganate by **barium sulphate**. C. W. Hempel found that a soln. of the permanganate oxidizes **mercurous salts** to mercuric salts; and E. Carstanjen, and J. E. Willm found that **thallous salts** are quantitatively oxidized—*vide infra*. In hot hydrochloric acid soln. the reaction is symbolized: $5TlCl+2KMnO_4+16HCl=5TlCl_3+2MnCl_2+2KCl+8H_2O$. A. J. Berry did not obtain a quantitative oxidation in sulphuric acid soln. According to A. Reynoso, **stannites** are oxidized by potassium permanganate to stannates, and **plumbites** to plumbates. A. E. Haswell found that **lead salts,** in the presence of zinc or mercuric oxide, are oxidized to form lead dioxide. According to B. C. Brodie, E. T. Allen, C. F. Schönbein, and H. N. Morse and co-workers, **lead dioxide,** in the presence of nitric acid, can precipitate the manganese completely from the soln.: $2HMnO_4+3PbO_2=2MnO_2+3PbO+3O_2+H_2O$. This reaction shows why in using W. Crum's process for oxidizing manganous salt soln. to permanganate—*vide supra*—for the detection of manganese it is necessary to work with a large excess of lead dioxide and a small proportion of manganese salt. S. Cloez and E. Guignet found that precipitated and washed hydrated **chromic oxide** is converted in the cold into a chromate; while E. Bohlig found that calcined chromic oxide is similarly oxidized when the liquid is boiled. A. Reynoso, and E. Donath obtained a similar result with **chromic salts.** H. A. Fales and P. S. Roller found that the reduction of MnO_4' by $Cr^{...}$ at $25\cdot1°$ in sulphuric acid soln. is autocatalytic and closely resembles the reduction of the permanganate by many organic acids. There is formed a sulphuric acid complex of $Mn^{....}$ and $Mn^{...}$. Oxidation by the latter is indirect in virtue of its unimolecular disengagement from the complex and its subsequent decomposition into $Mn^{....}$, which oxidizes $Cr^{...}$ rapidly. The temp. coeff. of the unimolecular reaction is $4\cdot01$ between 25° and 35°. $Mn^{....}$ also reacts with $Mn^{..}$, thus reverting to non-reactive $Mn^{...}$. In the interaction between $Mn^{..}$ and MnO_4' in acidic soln., the relative proportion of $Mn^{....}$ to $Mn^{...}$ increases as the ratio of $Mn^{..}$ to MnO_4' decreases. P. A. Tscheishwily found that chrome alum soln. are rapidly oxidized by permanganate. G. Forchhammer observed that **manganous carbonate** suspended in alkali-lye changes to green the red colour of a soln. of potassium permanganate, and a manganic salt is formed. M. Geloso and P. Dubois considered that the reduction of permanganates by manganous salts does not form a definite compound, but there is rather a continuous variation in the degree of oxidation of the pseudo-dioxides which are formed. Calcium carbonate neutralizes the acid which is formed, and part furnishes insoluble manganese carbonate. It also

exerts a surface effect. The equation used by A. Guyard, and J. Volhard for titrating soln. of **manganous sulphate** with potassium permanganate is : $3MnSO_4+2KMnO_4+2H_2O=5MnO_2+K_2SO_4+2H_2SO_4$. Observations on the subject were made by R. T. Colgate. According to H. Baubigny, the precipitation of manganese dioxide from an acid soln. of a manganous salt by potassium permanganate depends on the acidity, on the conc. of the salts, and on the temp. The presence of the acid retards the precipitation and may even completely prevent it. The amount of manganic salt which remains dissolved increases with the conc. of the acid, but diminishes as the temp. rises. The precipitate consists solely of manganese dioxide and contains no manganic oxide. W. M. Fischer noted that the titre of a standard soln. of potassium permanganate obtained by ferrous salts with oxalates is not the same as it is with a manganous salt. E. Divers attributed the difference to the fact that the precipitate contains less oxygen than is required for manganese dioxide, owing (i) to the adsorption of some manganous salt, and (ii) to the co-precipitation of some manganic acid : $4Mn^{..}+MnO_4'+8H^.$ $=5Mn^{...}+4H_2O$, followed by $2Mn^{...}=Mn^{..}+Mn^{....}$; some of the manganic ions escape the latter change and react : $Mn^{...}+3OH'=Mn(OH)_3$. To neutralize any acid formed in these hydrolytic changes, zinc oxide is added ; this is said to prevent any precipitation of manganic hydroxide and adsorption of manganous salts by the precipitated manganese dioxide. E. Cahen and H. F. V. Little recommended zinc sulphate and oxide ; and B. Reinitzer and P. Conrath, sodium acetate and acetic acid ; and P. B. Sarkar and N. R. Dhar showed that almost any other cation can be employed in place of zinc, and likewise also I. M. Kolthoff, who represented the reaction : $3Mn^.+2MnO_4'+2H_2O=5MnO_2+4H^.$; or $3MnSO_4+2KMnO_4+2H_2O$ $=5MnO_2+2H_2SO_4+K_2SO_4$, as represented by A. C. Sarkar and J. M. Dutta. J. Holluta and J. Obrist found that the reaction with manganous fluoride can be symbolized : $MnO_4'+4Mn^{..}+8H^.=5Mn^{...}+4H_2O$. A. Gorgeu said that he never observed the evolution of oxygen or chlorine in the action of manganous chloride on potassium permanganate, but J. G. F. Druce pointed out that oxygen is evolved when a conc. soln. of manganous sulphate is added to a sat. soln. of solid potassium permanganate ; and with barium permanganate much oxygen is given off : $MnSO_4+Ba(MnO_4)_2=BaSO_4+Mn_3O_4+2O_2$; and with conc. soln. of manganous chloride and potassium permanganate, chlorine is evolved : $2MnCl_2+2KMnO_4=2KCl+4MnO_2+Cl_2$. According to J. Heyrovsky, some dwimanganese or rhenium is evolved with the chlorine. M. Bobtelsky and D. Kaplan studied the action of various salts on the reaction between potassium permanganate and manganous sulphate. The reaction was also studied by N. R. Dhar, and J. G. F. Druce. The action of **manganese dioxide** on soln. of permanganates has been discussed in connection with permanganic acid and the action of hydrogen on the permanganates. G. Rapin, and R. T. Colgate made observations on the subject.

W. C. Birch, B. Suzuki and C. Hamada, and E. Müller and H. Möllering studied the reduction of permanganate by **ferrous salts.** Y. Ono compared the simultaneous oxidation of ferrous salts and manganous salts in soln. by potassium permanganate. The ferrous salt oxidized nearly twice as fast as the manganous salt. M. Bobtelsky and D. Kaplan studied the action of various salts on the reaction ; and F. L. Hahn and M. Frommer, the electrometric titration. M. A. von Reis and F. Wiggert, and C. Winkler found that **cobaltous salts** can be oxidized to cobaltic salts by permanganate. Numerous other salts can be oxidized to a higher state of oxidation, as indicated above in connection with permanganic acid, *e.g.* ferrous salts, and **molybdic salts** were found by I. Macagno to be converted into molybdates. The oxidizing reactions are utilized in numerous volumetric processes of analysis. M. Berthelot also utilized permanganate as an oxidizing agent for deducing heats of oxidation, etc.

A. Gorgeu found that if a soln. of 100 grms. of potassium hydroxide, 10 grms. of potassium permanganate, and 75 grms. of water be boiled until oxygen is no

longer evolved, and the soln. diluted with 150 to 200 grms. of water, and then mixed with 1 to 2 grms. of potassium permanganate, the liquid, on cooling and standing over conc. sulphuric acid, or in vacuo, deposits six-sided monoclinic plates which can be drained on porous tiles and dried at 100°. H. de Sénarmont found for the axial ratios of the crystals $a : b : c = 1.7176 : 1 : 1.3570$, and $\beta = 114° 39'$. The analysis corresponds with **potassium manganatopermanganate,** $K_2MnO_4.KMnO_4$. The crystals form a violet soln. with a 20 per cent. soln. of potassium hydroxide. Baryta-water added to the soln. gives a precipitate of barium manganate and a red soln. of potassium permanganate ; and the salt behaves towards acids like potassium manganate.

W. Muthmann obtained crystals of **rubidium permanganate,** $RbMnO_4$, from the soln. obtained by treating barium permanganate with rubidium sulphate. E. Moles and M. Crespi obtained the salt from a soln. of 5 grms. of potassium permanganate in 4.1 grms. of rubidium nitrate in 75 c.c. of water at 60° and cooled to 0°. They obtained $K = 1.566$ for the velocity of decomposition—*vide supra*, potassium permanganate. W. Muthmann found that the rhombic bipyramids have the axial ratios $a : b : c = 0.8311 : 1 : 0.6662$. T. V. Barker gave for the topic axial ratios $\chi : \psi : \omega = 4.0323 : 4.8517 : 6.4639$. For the isomorphism with the potassium salt, discussed by F. Rinne, W. Muthmann and O. Kuntze, and G. Tammann and A. Sworykin, *vide* Fig. 54. E. Moles and M. Crespi gave 3.23 for the sp. gr. ; and W. Muthmann gave 3.2348 for the sp. gr. and 63.228 for the mol. vol. The subject was discussed by A. F. Hallimond. I. I. Saslawsky gave 3.13 for the sp. gr., and calculated the contraction which occurs in the formation of the salt from its elements. E. Moles and M. Crespi found that the salt decomposes at 295° with the evolution of oxygen. W. Muthmann prepared **cæsium permanganate,** $CsMnO_4$, by the method employed for the rubidium salt ; and R. J. Meyer and H. Best, from the liquid obtained by treating silver permanganate with cæsium chloride. E. Moles and M. Crespi obtained the salt from a soln. of 3.2 grms. of potassium permanganate and 4 grms. of cæsium nitrate in 50 c.c. of water at 60° and cooled to 0°. They found $K = 1.628$ for the velocity of decomposition—*vide supra*, potassium permanganate. W. Muthmann found that the dark violet, rhombic, bipyramidal crystals have the axial ratios $a : b : c = 0.8623 : 1 : 0.6853$. T. V. Barker gave for the topic axial ratios $\chi : \psi : \omega = 4.2555 : 4.9009 : 6.7167$. W. Muthmann gave 3.5974 for the sp. gr., and 70.042 for the mol. vol. The subject was discussed by A. F. Hallimond. I. I. Saslawsky gave 3.55 for the sp. gr., and he calculated the contraction which occurs in forming the salt from its elements. E. Moles and M. Crespi gave 3.59 for the sp. gr., and found that the salt decomposes at 320° with the evolution of oxygen. W. Muthmann found that the crystals of rubidium and cæsium permanganates are isomorphous with those of potassium sulphate ; and T. V. Barker, F. Rinne, and G. Tammann and A. Sworykin discussed the isomorphism with the perchlorates. W. Muthmann found that the two salts are sparingly soluble in cold water, and freely soluble in hot water ; the solubility of the rubidium salt is between that of the potassium salt and that of the cæsium salt. A. M. Patterson gave for the solubility, S grms. in 100 c.c. of sat. soln. :

	$RbMnO_4$			$CsMnO_4$		
	2°	19°	60°	1°	19°	59°
S . .	0.46	1.06	4.68	0.097	0.23	1.25

E. Mitscherlieh, and H. Aschoff obtained deliquescent **copper permanganate,** $Cu(MnO_4)_2.8H_2O$, from the soln. obtained by the action of cupric sulphate on barium permanganate. E. Moles and M. Crespi prepared the copper salt by treating a soln. of copper chloride with silver permanganate and evaporating for crystallization. The trihydrate is very deliquescent. The sp. gr. of the salt is near 2.87 ; and it decomposes with the evolution of oxygen at 75°. E. Pflüger measured the absorption spectrum of dil. soln. of the salt. I. I. Saslawsky found the sp. gr. to be 2.87, and he calculated the contraction which occurs in forming

the salt from its elements. T. Klobb prepared **copper amminoperman-ganate**, which was not analyzed ; and the **copper pyridinopermanganate**, $Cu(MnO_4)_2.4C_5H_5N$. E. Mitscherlich obtained fine crystals of **silver permanganate**, $AgMnO_4$, by cooling a warm soln. of silver nitrate and potassium permanganate, but J. W. Retgers could not confirm this, and he obtained the silver salt as a black precipitate by mixing soln. of silver nitrate and potassium permanganate. E. Moles and M. Crespi, and G. Heikel used a similar process. J. Dewar and A. Scott said that the best way of making the salt is by crystallization from the soln. remaining after mixing barium permanganate and silver sulphate soln. The salt crystallizes well from hot water ; the crystals are stable and not hygroscopic. I. I. Saslawsky gave 4·27 for the sp. gr. of the salt, and he calculated the contraction which occurs in forming the salt from its elements. E. Mitscherlich found that the monoclinic prisms have the axial ratios $a : b : c = 1·4894 : 1 : 1·3703$, and $\beta = 93° 57'$. W. Büssem and K. Herrmann examined the X-radiograms of the monoclinic crystals, and found their unit cell has 4 mols., and $a = 5·66$ A., $b = 8·27$ A., and $c = 7·12$ A. The structure resembles a slightly deformed $KMnO_4$ lattice. The calculated density is 4·49. J. W. Retgers assumed that a rhombic, labile form exists. E. Moles and M. Crespi found that the sp. gr. is 4·27 ; and that the salt decomposes at 110° with the evolution of oxygen. They found $K = 0·183$ for the velocity of decomposition—*vide supra*, potassium permanganate. A. Lehmann discussed the reaction. A. Sieverts and H. Theberath represented the reaction $AgMnO_4 = AgMnO_3 + O$ at 30° and the reaction follows the rule $dx/dt = kx(a-x)$. The decomposition product, the nature of which has not been established, accelerates the reaction proportionally to its mass. The constants of the decomposition velocity of the various preparations are different. The presence of water has a very strong influence on this reaction. Dry silver permanganate decomposes very slowly, even at 50°, but small traces of water increase the decomposition velocity very much, whilst larger additions of water have little further influence. The addition of powdered pumice and the decomposition product of the reaction changes only the initial velocity. · Temp. has a very marked influence on the reaction. At 0°, even in the presence of water and the decomposition product, the decomposition does not take place. At 50° the decomposition process is no longer represented by the same equation as at 30° ; the tx curves for 50° are characterized by a long, almost straight line. At 30° an increase of 20° in the temp. of reaction causes the initial velocity to increase from 12 to 20 times, the mean velocity between 19 per cent. and 38 per cent. decomposition, 6·1–7·6 times, and between 38 per cent. and 57 per cent. decomposition, 3·4–4·3 times. C. N. Hinshelwood and E. J. Bowen found a period of acceleration in the thermal decomposition of the salt. According to E. Mitscherlich, 100 parts of water dissolve 0·917 part of the salt. E. Franke found the electrical conductivity, λ, of an eq. of the salt in v litres of water at 25° to be :

v .	. 64	128	256	512	1024
λ .	. 106·3	109·4	110·9	112·0	112·7

E. Mitscherlich found that the salt can be recrystallized from moderately warm soln., but it is decomposed by boiling water. A. Gorgeu said that the salt decomposes slowly in air, and in the presence of water, being slow at ordinary temp., but faster at 100° in the presence of water. At 135° the decomposition is attended by incandescence. According to A. Gorgeu, when hydrogen dioxide is added very slowly to a sat. aq. soln. of silver permanganate, a brown precipitate forms gradually until the liquid is decolorized. The reaction is represented by the equation : $2AgMnO_4 + 3H_2O_2 = Ag_2O.2MnO_2 + 3H_2O + 3O_2$. The precipitated silver manganite is rapidly attacked by excess of hydrogen dioxide. Hydrochloric acid is oxidized by the salt to form chlorine ; it is reduced by oxalic acid, ferrous salts, and arsenious acid, losing part of the oxygen as a gas. J. Krutwig found that chlorine decomposes the warm salt vigorously, forming silver chloride, manganese dioxide, and oxygen. T. Klobb could not prepare an ammine by the direct action

of ammonia, but he obtained **silver diamminopermanganate,** $AgMnO_4.2NH_3$, by adding conc. aq. ammonia to a soln. of a mol of potassium permanganate in water at 10°, and adding a mol of silver nitrate dissolved in ten times its weight of water. The crystalline precipitate is washed with ice-water and dried over calcium oxide. The violet powder consists of microscopic rhombic plates, sparingly soluble in cold water, more soluble in hot water. The salt explodes by percussion ; and on exposure it gradually decomposes, with the loss of ammonia. G. Bruni and G. Levi also prepared **silver triamminopermanganate,** $AgMnO_4.3NH_3$. T. Klobb also prepared the **silver pyridinopermanganates,** $AgMnO_4.2C_5H_5N$ and $2AgMnO_4.5C_5H_5N$.

E. Mitscherlich found that no salt is precipitated when soln. of potassium permanganate and barium chloride are mixed ; but E. Fleischer observed that if the mixed soln. is boiled, a reddish-violet precipitate is slowly formed, while the soln. remains violet. The precipitate can be washed with water and dried at 100°, but if the product be heated further, its colour fades, and finally becomes greyish-brown, without showing any sign of the formation of an intermediate green manganate. If the salt is mixed with 20 per cent. barium hydroxide and heated to redness, a bluish-green pigment is formed. According to L. Gmelin, an aq. soln. of potassium permanganate yields with baryta-water a violet mixture, which ultimately becomes colourless, and deposits a blue precipitate. This precipitate retains its colour when washed and dried. The blue colour suggests that it is a mixture of barium manganate and permanganate. When it is decomposed by dil. sulphuric acid, it yields permanganic acid and a precipitate of hydrated manganese dioxide. H. Aschoff, however, said that a soln. of potassium permanganate and baryta-water, when allowed to stand a long time, deposits microscopic crystals of barium manganate. E. Mitscherlich, F. Wöhler, and C. Fromherz prepared **barium permanganate,** $Ba(MnO_4)_2$, by passing carbon dioxide into water with barium manganate in suspension and evaporating the filtered soln. for crystallization—R. Böttger used hot water. H. Aschoff added that the process is slow and tedious, and the carbon dioxide is not without action on the barium permanganate which is formed. H. Aschoff obtained crystals of the permanganate from the soln. obtained. when silver permanganate is treated with the calculated quantity of barium chloride. G. Rousseau and B. Bruneau treated a sat. soln. of potassium permanganate with hydrofluosilicic acid, and saturated the liquor, filtered through asbestos, with milk of baryta ; the dissolution of the baryta is followed by the precipitation of some barium fluosilicate. The soln. after standing half an hour is decanted and evaporated for barium permanganate. The preparation of the alkaline earth permanganates was described by R. E. Wilson and co-workers. E. Moles and M. Crespi obtained barium permanganate from a soln. of 3·62 grms. of barium chloride in 50 c.c. of water and 8 grms. of silver permanganate. The filtered soln. was evaporated for crystallization. W. Muthmann recommended the following process :

100 grms. of potassium permanganate are treated with 140 grms. of barium nitrate dissolved in 1·5 litres of boiling water, and barium hydroxide is added in portions of 20 grms. until no further evolution of oxygen takes place. The whole is then warmed until the soln. has become colourless, the precipitate of barium manganate (containing also some dioxide and carbonate) is collected, washed five times by decantation with 5 litres of boiling water, collected on the filter-pump, washed ten times more with boiling water, suspended in a litre of water, and carbon dioxide and superheated steam passed into the mixture for 10 hrs. The soln. is then filtered twice through an asbestos filter ; it contains 65 to 80 grms. of barium permanganate.

E. Mitscherlich said that the acicular crystals are almost black, and are stable in air. The rhombic crystals are isomorphous with those of anhydrous sodium sulphate and selenate, as well as with silver permanganate. I. I. Saslawsky gave 3·77 for the sp. gr., and he calculated the contraction which occurs in forming the salt from its elements. E. Moles and M. Crespi found that the sp. gr. of the salt is 3·77 ; and it decomposes at 220° with the evolution of oxygen. The velocity

constant is $K=0.088$—*vide supra*, potassium permanganate. E. Franke found the electrical conductivity, λ, of an eq. of the salt, $\frac{1}{2}Ba(MnO_4)_2$, in v litres of water at 25° to be :

v .	. 32	64	128	256	512	1024
λ .	. 87·62	93·80	98·60	101·3	105·5	107·3

C. Fromherz said that the red, aq. soln. with baryta-water forms a violet liquid, which after a time loses its alkaline reaction and on evaporation below 50° furnishes green barium manganate. According to A. Gorgeu, if hydrogen dioxide is added to a neutral soln. of barium permanganate, a brownish-yellow precipitate is formed, which contains all the barium, chiefly in the form of manganite, but with a small quantity of the manganate. If the permanganate is previously mixed with 2 to 4 eq. of barium hydroxide in soln., all the barium is precipitated in the form of the deep blue manganate on addition of hydrogen dioxide. An excess of hydrogen dioxide exerts a powerful reducing action on the manganate and a feebler action on the manganite.

E. Mitscherlich prepared **strontium permanganate,** $Sr(MnO_4)_2.H_2O$, by the method employed for the barium salt ; and H. Aschoff obtained it by evaporating the soln. obtained from the action of strontium chloride on silver permanganate. I. I. Saslawsky gave 2·66 for the sp. gr., and he calculated the contraction which occurs in forming the salt from its elements. The crystals are deliquescent. E. Moles and M. Crespi obtained the salt from a soln. of 2·14 grms. of dihydrated strontium chloride and 5 grms. of silver permanganate in 25 c.c. of water. The sp. gr. is 2·75 ; and the salt decomposes at 175° with the evolution of oxygen. C. Fromherz said that the violet aq. soln. becomes pale green when treated with an excess of strontium hydroxide. E. Franke found that the electrical conductivity, λ, of a soln. of an eq. of the salt, $\frac{1}{2}Sr(MnO_4)_2$, in v litres of water at 25° is :

v .	. 64	128	256	512	1024
λ .	. 101·0	104·7	107·6	109·6	110·3

E. Mitscherlich, and H. Aschoff prepared **calcium permanganate,** $Ca(MnO_4)_2.5H_2O$, by the methods just indicated for the strontium salt. E. Delaurier also obtained it by the prolonged heating of calcium manganate in air. E. Moles and M. Crespi used the process they employed for the strontium salt. The Chemische Fabrik Griesheim-Elektron obtained by electrolyzing in a diaphragm cell a soln. of an alkali manganate or permanganate together with a non-alkali metal hydroxide or halide. I. I. Saslawsky gave 2·4 for the sp. gr., and he calculated the contraction which occurs in forming the salt from its elements. The permanganic acid formed at the anode unites with the metal hydroxide or halide. E. Delaurier said that calcium permanganate readily fuses. E. Adinolfi discussed the absorption spectrum of the salt. A. Kailan studied the action of radium rays on the permanganate. E. Franke found the electrical conductivity, λ, of a soln. of an eq. of the salt, $\frac{1}{2}Ca(MnO_4)_2$, in v litres of water at 25° to be :

v .	. 64	128	256	512	1024
λ .	. 97·21	101·4	104·9	108·8	111·7

E. Wilke-Dörfurt and H. G. Mureck prepared **calcium hexantipyrinopermanganate,** $[Ca(COC_{10}H_{12}N_2)_6](MnO_4)_2$. E. Moles and M. Crespi prepared **beryllium permanganate,** $Be(MnO_4)_2$, from a soln. of beryllium chloride and the calculated quantity of silver permanganate which, on crystallization, furnishes the *penta-hydrate*, $Be(MnO_4)_2.5H_2O$. The evolution of oxygen from the salt begins at 60°. I. I. Saslawsky calculated the contraction which occurs in forming the salt from its elements. E. Mitscherlich, and H. Aschoff also prepared **magnesium permanganate,** $Mg(MnO_4)_2.6H_2O$, from the soln. obtained by decomposing silver permanganate with magnesium chloride, or barium permanganate with magnesium sulphate. I. I. Saslawsky gave 2·18 for the sp. gr., and he calculated the con-

traction which occurs in forming the salt from its elements. E. Moles and M. Crespi prepared the salt by a similar method to that used for the beryllium salt, and after drying obtained crystals of the *tetrahydrate*, $Mg(MnO_4)_2.4H_2O$. The sp. gr. of the salt is 2·18; and it decomposes with the evolution of oxygen at 150°. The deliquescent crystals, according to A. Michael and W. W. Garner, are insoluble in chloroform, carbon tetrachloride, benzene, toluene, nitrobenzene, ether, ligroin, and carbon disulphide, but soluble in methyl alcohol, acetone, pyridine, and glacial acetic acid. The soln. in glacial acetic acid is a more active oxidizing agent for organic substances than soln. in pyridine. T. Klobb prepared **magnesium amminopermanganate**, which was not analyzed. E. Mitscherlich, T. Klobb, H. Aschoff, and C. Kupffer obtained **zinc permanganate**, $Zn(MnO_4)_2.6H_2O$, by treating barium permanganate with a soln. of zinc sulphate and evaporating the filtered liquid; and J. F. Martenson, and G. Heikel, by treating a hot soln. of silver permanganate with a neutral soln. of zinc chloride and evaporating the filtered soln. for crystallization. E. Moles and M. Crespi obtained it as a tetra- or pentahydrate as in the case of the beryllium salt. F. Stolba obtained a soln. of the salt by adding crystalline zinc fluosilicate to a soln. of potassium permanganate. L. H. Bernagau described commercial samples with 8 to 32 per cent. insoluble matter; and J. Biel, samples with up to 92 per cent. of zinc sulphate. The needle-like crystals are dark brown. I. I. Saslawsky gave 2·47 for the sp. gr., and calculated the contraction which occurs in forming the salt from its elements. J. F. Martenson found that the crystals can be preserved if they are free from zinc chloride, otherwise they soon begin to develop chlorine. All but one mol. of water are given off at 100° in vacuo, and the last mol. can be driven off only with the decomposition of the salt. E. Moles and M. Crespi found that the sp. gr. is 2·47; and that the salt decomposes at 95° with the evolution of oxygen. C. Kupffer said that the salt decomposes with the evolution of oxygen at 140°; and T. Klobb, that the salt forms manganese dioxide when it is heated with boric oxide in a current of dry air. J. F. Martenson found that when heated in a glass tube, what appears to be a purple vapour is evolved. The salt deliquesces in moist air; it is freely soluble in water; and the aq. soln. can be kept a long time without decomposition. T. Klobb obtained **zinc tetramminopermanganate**, $Zn(MnO_4)_2.4NH_3$, by mixing 40 c.c. of a 50 per cent. soln. of zinc sulphate, 60 c.c. of ammonia, and 100 c.c. of a soln. of potassium permanganate saturated at 10°. The liquid is filtered rapidly, and dried in the cold over sulphuric acid. The violet crystals are deliquescent. The corresponding **zinc pyridinopermanganate**, $Zn(MnO_4)_2.4C_5H_5N$, was also prepared. C. Fromherz observed no precipitation occurs when potassium permanganate is treated with cadmium chloride. T. Klobb prepared **cadmium permanganate**, $Cd(MnO_4)_2.8H_2O$, by crystallization from a soln. of cadmium sulphate and barium permanganate; E. Moles and M. Crespi obtained the *hexahydrate* by the method used for the beryllium salt. Its sp. gr. is 2·81; and it decomposes with the evolution of oxygen at 95°. The velocity constants for the decomposition are $k=0.0212$, $k_1=0.100$, and $k_2=0.111$—*vide supra*, potassium permanganate. T. Klobb obtained **cadmium tetramminopermanganate**, $Cd(MnO_4)_2.4NH_3$, from a soln. of potassium permanganate sat. with ammonia, and a cadmium salt. In a few days the black crystals form a brown mass. The salt detonates by percussion. The corresponding **cadmium pyridinopermanganate**, $Cd(MnO_4)_2.4C_5H_5N$, was also prepared.

E. Wilke-Dörfurt and H. G. Mureck prepared **aluminium hexantipyrinopermanganate**, $[Al(COC_{10}H_{12}N_2)_6](MnO_4)_3$. The action of permanganates on cerous salts has been discussed in connection with permanganic acid. F. T. Frerichs and J. L. Smith reported the formation of **didymium permanganate**, $Di(MnO_4)_3.21H_2O$, slightly soluble in water; and similarly **lanthanum permanganate**, $La(MnO_4)_3.21H_2O$; but P. T. Cleve could not obtain either salt. E. Carstanjen found that neutral soln. of thallous sulphate and potassium permanganate form a reddish-brown precipitate consisting of thallic hydroxide and thallous permanganate. The permanganate is reduced directly to a manganous state without the

formation of intermediate oxides. In very dil. soln. the thallic hydroxide predominates, and with conc. soln. **thallous permanganate,** $TlMnO_4$. J. E. Willm made some observations on this subject, and T. V. Barker said that thallous permanganate could not be prepared owing to the oxidation of the thallous salt by the permanganate. R. J. Meyer and H. Best obtained black prismatic crystals of the salt by evaporating over sulphuric acid the filtered liquid resulting from the action of a soln. of thallous sulphate on an eq. proportion of barium permanganate. The salt is liable to decompose into thallic oxide during the evaporation. C. Forchhammer obtained a brown precipitate, thought to be **lead permanganate,** $Pb(MnO_4)_2$, by treating a soln. of lead nitrate with potassium permanganate. The salt is soluble in nitric acid. E. Wilke-Dörfurt and co-workers prepared **chromic hexantipyrinopermanganate,** $[Cr(COC_{10}H_{12}N_2)_6](MnO_4)_3$; also **chromic hexamminopermanganate,** $[Cr(NH_3)_6](MnO_4)_3$; A. Werner and D. Kalkmann, and E. Wilke-Dörfurt and K. Niederer, **chromic hexacarbamidopermanganate,** $[Cr(CON_2H_4)_6](MnO_4)_3$; **chromic hexacarbamidosulphatopermanganate,** $[Cr(CON_2H_4)_6](SO_4)MnO_4$; and **chromic hexacarbamidodichromatopermanganate,** $[Cr(CON_2H_4)_6](Cr_2O_7)MnO_4$. The **molybdatopermanganates** have been discussed in connection with the molybdates.

For the **manganous permanganates** of A. Guyard, *vide supra.* C. Fromherz observed no precipitation occurs when a soln. of nickelous chloride is treated with potassium permanganate. T. Klobb obtained **nickel amminopermanganate,** as a crystalline precipitate, by dissolving a mol of potassium permanganate in the necessary quantity of water at 0°, saturating the soln. at 0° with ammonia, and adding a mol of nickel nitrate dissolved in ten times its weight of water. He also prepared **nickel pyridinopermanganate,** $Ni(MnO_4)_2.4C_5H_5N$. T. Klobb, and E. Wilke-Dörfurt and co-workers prepared **cobaltic hexamminopermanganate,** $[Co(NH_3)_6](MnO_4)_3$, or *luteocobaltic permanganate,* by mixing a warm, conc. soln. of a mol of cobaltic hexamminochloride with 12 mols of potassium permanganate; it separates in the form of a precipitate mixed with a salt which crystallizes in hexagonal plates and is formed in greater proportion when the permanganate is not in excess. The second salt can be removed by treatment with cold water and the cobaltic hexamminopermanganate is recrystallized from water at 60°. It then forms very brilliant black tetrahedra, only slightly soluble in cold water, but more soluble in hot water, with partial decomposition. When heated it detonates, and it also explodes when struck. With hydrochloric acid it yields manganous chloride and cobaltic hexamminochloride. If a warm soln. of 8 mols of cobaltic hexamminochloride be treated with a soln. of a mol of cobaltic hexamminopermanganate, filtered rapidly, and allowed to cool, **cobaltic hexamminodichloropermanganate,** $[Co(NH_3)_6]Cl_2(MnO_4)$, separates in small black lamellæ with the form of a regular hexagon, red or brown by transmitted light. It is very unstable, and is decomposed by water with removal of the hexamminochloride, but dissolves without decomposition in a soln. of cobaltic hexamminochloride. When heated rapidly it detonates, but it does not explode on percussion. The corresponding **cobaltic hexamminodibromopermanganate,** $[Co(NH_3)_6]Br_2(MnO_4)$, is prepared in a similar manner, or by mixing warm soln. of 3 mols of potassium permanganate and a mol of cobaltic hexamminobromide. The salt furnishes hexagonal plates, which are more stable than the corresponding chloride and are not decomposed by boiling water. The salt which separates in violet hexagonal plates in the preparation of the hexamminopermanganate is **potassium cobaltic hexamminochlorodipermanganate,** $[Co(NH_3)_6]Cl(MnO_4)_2.2KCl$. It separates slowly from a cold, conc. soln. of a mol of cobaltic hexamminochloride and 3 mols of potassium permanganate. It furnishes violet hexagonal lamellæ, which dissolve freely in water, with partial decomposition into its constituents. When heated it behaves like the preceding salts. It may be regarded as a compound of cobaltic hexamminopermanganate and cobaltic hexamminochloride with potassium chloride. It can also be formed by dissolving cobaltic hexamminochloropermanganate in

potassium chloride soln., or by the action of cobaltic hexamminopermanganate on a large excess of potassium chloride.

§ 16. Manganese Fluorides

Two well-defined manganese fluorides have been prepared, namely, *manganese difluoride*, MnF_2, and *manganese trifluoride*, MnF_3; while a third fluoride, *manganese tetrafluoride*, MnF_4, can be obtained in soln. in hydrofluoric acid, and in the form of well-defined complex salts. The complex salts of manganese tetrafluoride of the type R_2MnF_6 are called *fluomanganites*, so that the complex salts of manganese trifluoride of the type R_2MnF_5 have to be called by the unfortunate term *fluohypomanganites*.

J. J. Berzelius [1] evaporated a soln. of manganous carbonate in hydrofluoric acid, and obtained small, pale amethyst-red, ill-defined crystals of **manganous fluoride,** or **manganese difluoride,** MnF_2. C. Brunner, and O. Unverdorben also prepared this salt in an analogous manner. H. Moissan and A. Venturi avoided warming the soln. during the action; they also said that the salt is best made by dissolving manganese in dil. hydrofluoric acid contained in a silver basin, kept cool by a rapid current of cold water; on boiling the soln., manganous fluoride is deposited as a white crystalline powder, which is collected and dried at 120°. The salt is also formed as a rose-coloured fused mass when gaseous hydrogen fluoride is passed over metallic manganese; and it is also formed when a current of hydrogen fluoride is passed over hydrated manganese fluosilicate at 1000°. F. Röder prepared manganous fluoride, in small red needles, by melting a mixture of manganous chloride and sodium fluoride and chloride, and removing the soluble matter by leaching the product with water; E. Defacqz also obtained manganous fluoride by melting a fluoride of an alkaline earth with manganous chloride, bromide, or iodide. The reaction is reversible, so that an excess of the fluoride is needed. P. Nuka prepared the anhydrous salt by heating the ammonium salt NH_4MnF_3 to 300° in a current of carbon dioxide.

According to H. Moissan and A. Venturi, manganous fluoride may be recrystallized from fused manganous chloride, when it forms rose-coloured prisms which, according to A. de Schulten, are isomorphous with sellaite, MgF_2. According to A. E. van Arkel, the X-radiograms of manganous fluoride correspond with the rutile or tetragonal type of space-lattice with 2 mols. per unit cell; the cell has a base $a=4.88$ A., and a height $c=3.29$ A. A. Ferrari gave $a=4.865$ A., and $c=3.284$ A., and $a:c=1:0.675$; the calculated **specific gravity** is 3.97; W. Biltz and E. Rahlfs found 3.891 for the sp. gr. at 25°/4°, and 23.88 for the mol. vol. H. Moissan and A. Venturi found the sp. gr. to be 3.98, and the **melting-point** 856°; and A. Ferrari discussed some relations of the m.p. According to J. J. Berzelius, it is not decomposed at a red-heat. W. Herz discussed the entropy and vibration frequency. E. Petersen calculated for the **heat of neutralization** $(Mn(OH)_2, 2HF_{aq.})$ $=28,064$ cals.; and for the **heat of formation,** $(Mn, F_2, H_2O)=156.8$ Cals., while M. Berthelot obtained 155.5 Cals.; H. von Wartenberg, 206.1 Cals.; and K. Jellinek and R. Koop, 170.9 Cals. G. Beck studied the energy of the salt. For the anodic oxidation of the salt, *vide supra*, permanganic acid. J. Liebknecht and A. P. Wills gave 162×10^{-6} mass unit for the **magnetic susceptibility** of aq. soln. at 18°.

H. Moissan and A. Venturi found that the salt is completely reduced by **hydrogen** at 1000°, but only very slowly at 500°. K. Jellinek and A. Rugat found that in the reaction $MnF_2 + H_2 \rightleftharpoons Mn + 2HF$, the values of $\log (p^2_{HF}/p_{H_2})$ at the absolute temp. 873°, 975°, and 1073° are respectively -4.96, -4.43, and -3.99; $\log (p^2_{HF}/p_{H_2}p_{F_2})$, 33.12, 29.83, and 27.15; and those of $\log p_{F_2}$, -38.08, -34.26, and -31.14, where p_{F_2} is the vap. press. of the metal fluoride. According to H. Moissan and A. Venturi, dry **oxygen** acts only slowly at 400°, but at 1000° the salt is completely decomposed to form the tritatetroxide. Manganous fluoride is almost insoluble in **water.** R. H. Carter found that 100 c.c. of aq. soln. contained 0.186 grm. MnF_2 at 25°, and for the sat. soln., $p_H = 7.0$. W. Biltz and E. Rahlfs prepared the *tetrahydrate* by drying it at room temp. The sp. gr. of the tetra-hydrate is 2.036 at 25°/4°, and the mol. vol. 81.04. H. Moissan and A. Venturi

found that if the salt be boiled with water, manganese oxyfluoride and hydrofluoric acid are first formed, but if the boiling be prolonged, a mixture of hydrated manganese fluoride and oxyfluoride is deposited; between 1200° and 1300° steam converts manganous fluoride into manganous oxide. P. Nuka found that 100 grms. of an aq. soln. of the tetrahydrate contains 1·05 grms. of MnF_2. The salt is converted by **fluorine**—*vide infra*—into the trifluoride—slowly in the cold, rapidly when heated; it is not attacked by **chlorine** in the cold, but at 1200° some manganous chloride is formed, but there is no evidence of the formation of a *manganese chlorofluoride*. With chlorine water, or **bromine** water, hydrofluoric acid and manganese dioxide are formed. J. J. Berzelius found that the salt is soluble in water containing **hydrofluoric acid**; but H. Moissan and A. Venturi found that it is not perceptibly soluble in conc. hydrofluoric acid. By evaporating the aq. soln. acidified with hydrofluoric acid, F. H. Edmister and H. C. Cooper obtained crystals of **manganous pentahydroheptafluoride**, $MnF_2.5HF.6H_2O$. They are not permanent in air, but decompose with the loss of hydrogen fluoride. The crystals are rhombohedral, with prismatic cleavage, and uniaxial. The sp. gr. is 1·921. H. Moissan and A. Venturi said that cold, conc. **hydrochloric acid** dissolves manganous fluoride freely, but the dil. acid acts only slowly. When the salt is heated to 1000° in an atm. of **sulphur**, green manganous sulphide is rapidly formed; and similarly with **hydrogen sulphide**. The salt is decomposed by sulphuric acid with the liberation of hydrogen fluoride. G. Gore, and E. C. Franklin and C. A. Kraus said that manganous fluoride is sparingly soluble in liquid **ammonia,** and H. Moissan and A. Venturi, that **manganous tritadiamminofluoride,** $3MnF_2.2NH_3$, is formed as a crystalline powder which slowly evolves ammonia; and manganese fluoride is partially reduced when heated at 1200° in an atm. of ammonia. W. Biltz and E. Rahlfs prepared **manganese aquopentamminodifluoride,** $MnF_2.H_2O.5NH_3$, of sp. gr. 1·477 at 25°/4°; mol. vol. 132·6; vap. press. 39·2 mm. at −21°, 80·0 mm. at −11°, and 173·0 mm. at 0°; and heat of formation 9·6 Cals. Similarly, **manganese aquoamminodifluoride,** $MnF_2.H_2O.NH_3$, has a sp. gr. of 2·291 at 25°/4°; a mol. vol. of 55·86; a vap. press. of 10·5 mm. at 25°, 20 mm. at 34·4°, 43·0 mm. at 46°, and 108·0 mm. at 61°; and a heat of formation of 12·3 Cals. They also found evidence of the formation of **manganese aquohemiamminodifluoride,** $MnF_2.H_2O.\frac{1}{2}NH_3$. According to H. Moissan and A. Venturi, manganous fluoride is freely soluble in conc. **nitric acid.** Manganous fluoride is decomposed at 1000° by **boron** to form boron fluoride and manganese boride; and by **silicon** to form manganese silicide and silicon fluoride. E. Wilke-Dörfurt and H. G. Mureck prepared **manganous hexantipyrinoborofluoride,** $[Mn(COC_{10}H_{12}N_2)_6](BF_4)_2$. J. J. Berzelius, J. C. G. de Marignac, and F. Stolba described a fluosilicate, $MnF_2.SiF_4.6H_2O$, which was formed by the action of **silicon tetrafluoride**; J. J. Berzelius, and J. C. G. de Marignac, a fluotitanate, $MnF_2.TiF_4.6H_2O$, by the action of **titanium tetrafluoride**; and J. C. G. de Marignac, a fluostannate, $MnF_2.SnF_4.6H_2O$, by the action of **stannic fluoride**; and the fluozirconates $MnF_2.ZrF_4.5H_2O$ and $2MnF_2.ZrF_4.6H_2O$ by the action of **zirconium tetrafluoride.** According to H. Moissan and A. Venturi, manganous fluoride is not decomposed by **carbon** at 1200°. The salt is practically insoluble in **alcohol,** and in **ether**; while it is but slowly dissolved by **acetic acid.** A. Naumann said that the salt is insoluble in **acetone**; and H. Moissan and A. Venturi observed that manganous fluoride is reduced to impure metal, without incandescence, when it is heated with **sodium, potassium, magnesium,** or **aluminium.** A boiling soln. of **alkali hydroxide** forms alkali fluoride and hydrated manganous oxide. The salt is also decomposed by fused **alkali carbonate** or alkali hydroxide, and by **potassium nitrate or chlorate.** E. Defacqz found that the reaction with fused **calcium chloride** is reversible.

According to J. L. Gay-Lussac and L. J. Thénard, the white precipitate obtained by treating an aq. soln. of manganous sulphate with potassium fluoride is, according to J. J. Berzelius, **potassium manganous fluoride**; it is said to be insoluble in

water, but freely soluble in acids.   C. E. Saunders could not prepare this salt.
J. J. Berzelius also mentioned a **sodium manganous fluoride,** sparingly soluble in
water.   P. Nuka prepared **ammonium manganous fluoride,** NH_4MnF_3.   A sat.
soln. of the salt becomes turbid at 60° and deposits anhydrous MnF_2.   At 290°
to 300°, in an atmosphere of carbon dioxide, the complex salt furnishes manganous
fluoride.

According to H. Moissan,[2] metallic manganese is attacked by fluorine at the
ordinary temp., but the reaction is limited by the formation of a layer of fluoride
on the surface of the metal.   If the manganese be finely powdered, the reaction
takes place with incandescence, but the fluoride formed is partly volatilized and
decomposed, so that the product is not of constant composition.   Manganous
fluoride is also attacked by fluorine, but the reaction is never complete, whilst with
manganous chloride it is difficult to expel the whole of the chlorine.   With man-
ganous iodide, however, the reaction is much more regular, and **manganese tri-
fluoride,** or manganic fluoride, MnF_3, is produced in crystals which are pseudomorphs
after the parent iodide.   The crystals have a **specific gravity** of 3·54.   E. Petersen
found that the **heat of solution** is very small; and the **heat of neutralization**
$(Mn(OH)_3,3HF)=25\cdot8$ Cals.   A. Travers made this salt.   H. Moissan found that
when the trifluoride is heated it decomposes, forming manganous fluoride and
fluorine; it is reduced by **hydrogen,** below redness, forming hydrogen and man-
ganous fluorides; K. Jellinek and R. Koop studied the equilibrium in the reduc-
tion of manganic to manganous fluoride by hydrogen.   According to H. Moissan,
manganic fluoride is decomposed by **oxygen** at a red-heat, forming black crystalline
manganese oxide; and it reacts with **water,** forming manganous fluoride, hydro-
fluoric acid, and a hydrated manganese oxide in proportions dependent on the
proportion of water employed.   At ordinary temp. **chlorine** has no action on
manganese trifluoride, but when heated a ternary compound is formed; and
similarly also with **bromine,** and with **iodine,** which forms a red compound.   If
heated in an atmosphere of **hydrogen chloride,** manganous chloride, hydrogen
fluoride, and chlorine are formed; and with **hydrochloric acid** a dark brown soln.
is produced which is decomposed by water.   When the trifluoride is treated with
boiling **sulphur,** sulphur and manganous fluorides are formed; **hydrogen sulphide**
reacts readily at 200° with manganese trifluoride, and so do **sulphur monochloride,**
and **sulphuryl chloride;** while **sulphuric acid** forms a dark brown soln. readily
decomposed by water; and similarly with **nitric acid.**   Manganese trifluoride reacts
with **phosphorus,** at a slightly elevated temp., forming phosphorus tri- and penta-
fluorides; with **phosphorus trichloride** it yields phosphorus fluochloride; and with
phosphorus pentachloride it yields phosphorus pentafluoride.   When heated with
arsenic, the reaction furnishes arsenic trifluoride.   When heated with **boron,** the
reaction furnishes boron trifluoride; and with **silicon,** silicon tetrafluoride.   When
manganese trifluoride is heated in a **glass** vessel, there is a violent reaction, silicon
tetrafluoride is set free, and a mixture of manganese fluoride and oxyfluoride
remains.   When the salt is heated with **carbon,** carbon tetrafluoride is formed; with
carbon tetrachloride the products are manganous fluoride, chlorine, and carbon
tetrafluoride.   No action was observed at 100° with **benzene, turpentine, chloro-
form, alcohol,** and **ether.**

O. T. Christensen, and G. Gore found that the higher manganese oxides are
attacked by hydrofluoric acid with difficulty; but J. J. Berzelius observed that
the mineral manganite, when in the form of an impalpable powder, dissolves in the
acid, forming a red soln., which, when evaporated spontaneously, furnishes dark
brown prisms which appear ruby-red by transmitted light.   The powder is also
ruby-red.   O. T. Christensen, and J. Nicklès obtained a similar product from a
soln. of artificially prepared manganese hemitrioxide in hydrofluoric acid.   The
salt can be recrystallized from hydrofluoric acid.   The analyses agree with **tri-
hydrated manganic fluoride,** $MnF_3.3H_2O$.   According to E. Müller and P. Koppe,
a fluoride of tervalent manganese is readily obtained by the action of permanganates

on a manganous salt in presence of hydrofluoric acid, the reaction being: $MnO_4'+4Mn^{..}+8H^{.}=5Mn^{...}+4H_2O$. The difference between the reactions in presence of hydrofluoric and sulphuric acids is due to the conversion of $Mn^{...}$ into a complex fluoride ion in the one case; then the manganese dioxide, which is insoluble in hydrofluoric acid, dissolves if a manganous salt is also present. Manganic fluoride, free from potassium, may be obtained by electrolyzing a neutral soln. of a manganous salt and dissolving the oxide precipitated at the anode in hydrofluoric acid. The difficulty of observing the end-point in presence of the pink manganic salt makes it impossible to obtain accurate results on titrating manganese with permanganate in presence of hydrofluoric acid. The reaction appears, however, to be nearly complete in a warm soln. L. von Putnoky and B. von Bobest showed that the trifluoride is a secondary product of the anodic oxidation of manganous fluoride—*vide supra*, permanganic acid. J. J. Berzelius found that the salt can be completely dissolved in a small proportion of water, but with more water, or if the clear aq. soln. be boiled, hydrolysis occurs and a basic salt is precipitated; on cooling the soln. the precipitate is redissolved. The aq. soln. gives a precipitate of hydrated manganic oxide, free from fluoride, when it is treated with ammonia; and, according to J. Nicklès, a precipitate is formed when potassium fluoride is added to the aq. soln.

F. Olsson obtained two series of complex salts of the type $RMnF_4.nH_2O$ and R_2MnF_5 by the union of manganic fluoride with an organic base—quinoline, guanidine, tetramethylammonium, dimethylamine, diethylamine, ethylamine, propylamine, and ethylenediamine. O. T. Christensen added a soln. of hydrated manganese hemitrioxide in hydrofluoric acid to a conc. soln. of ammonium fluoride, and obtained crystals of **ammonium manganic pentafluoride**, $2NH_4F.MnF_3$, or $(NH_4)_2MnF_5$. If the soln. be too dilute, evaporation may be necessary before crystallization can take place. The salt can be recrystallized from water containing ammonium fluoride or hydrofluoric acid. The dark red, almost black, prismatic crystals were also prepared by J. Nicklès, who stated that they are decomposed by heat into manganous fluoride and oxide. O. T. Christensen found that the hydrofluoric acid soln. gives a dirty red precipitate with calcium or strontium chloride, and with barium chloride, a pale red precipitate which turns violet. O. T. Christensen, and J. Nicklès also prepared **sodium manganic pentafluoride**, Na_2MnF_5, in an analogous manner. The crystals under the microscope appear to be rectangular plates. The salt is sparingly soluble in water. It melts when heated, and retains its red colour. J. Nicklès thought the salt was a compound of manganese tetrafluoride. O. T. Christensen, and J. Meyer prepared **potassium manganic pentafluoride**, $K_2MnF_5.H_2O$, by adding an excess of potassium fluoride to a filtered soln. of hydrated manganese hemitrioxide in hydrofluoric acid. The rose-red precipitate is washed with water containing hydrofluoric acid and dried on platinum. The same salt is prepared by heating manganese dioxide with potassium hydrofluoride, and by precipitation from a soln. of potassium fluoride with a soln. of manganese dioxide in hydrofluoric acid. E. Müller and P. Koppe found that by mixing, in the order given, a soln. of 8·9 grms. of manganous sulphate in 30 c.c. of water, 8 c.c. of 40 per cent. hydrofluoric acid, a soln. of 1·58 grms. of potassium permanganate in 25 c.c. of water, and one of 5·8 grms. of potassium fluoride in 20 c.c. in a platinum basin, a salt is obtained which, after washing with hydrofluoric acid and alcohol and drying in a desiccator, has the composition $2KF.MnF_3.H_2O$. According to O. T. Christensen, the salt is decomposed by water at the ordinary temp.; and also by hydrogen dioxide. Hydrochloric acid decomposes it with the production of a dark colour; when the soln. is treated with water, the soln. becomes transparent and bright yellowish-red. The salt dissolves in sulphuric acid, yielding an amethyst-coloured liquid, which becomes red on the addition of water. It forms a brown soln. with oxalic or tartaric acid and the soln. is reduced by boiling. The soln. in phosphoric acid is red. The salt is identical with the one to which J. Nicklès ascribed the formula $2KF.MnF_4$. I. Bellucci obtained

the salt $K_2MnF_5.H_2O$ by the action of nitrous acid in the presence of hydrofluoric acid on either potassium permanganate or on a manganous salt, the nitrous acid acting in the former case as a reducing agent and in the latter as an oxidizing agent. The formation of this salt causes fallacious results in the determination of nitrous acid by potassium permanganate in the presence of fluoride. F. Fichter and E. Brunner observed that when a suspension of manganous fluoride in water is treated with a current of fluorine, it slowly dissolves, forming a red liquid, from which a sat. soln. of potassium fluoride precipitates the complex pentafluoride as a pink crystalline powder. There is here the possibility of a direct oxidation without the formation of an intermediate product; but the reaction is far from being complete: the formation of hydrogen dioxide can be detected from the beginning, and, moreover, we have a complicated equilibrium between manganous and manganic fluorides, hydrofluoric acid, and hydrogen dioxide, where the temp., concentration, and duration of the treatment with fluorine are of influence. Sometimes the pink colour diminishes even during the experiment. G. Wiedemann studied the magnetic properties of the potassium salt. O. T. Christensen prepared **silver manganic pentafluoride,** $Ag_2MnF_5.4H_2O$, by evaporating a mixed soln. of the component salts. The crystals are almost black, and they lose their water at 110°, along with a trace of hydrogen fluoride; **zinc manganic pentafluoride,** $ZnMnF_5.4$(and 7)H_2O, was also prepared. F. Ephraim and L. Heymann's attempts to prepare **thallous manganic pentafluoride,** analogous to the alkali salts, furnished **thallous manganosic tridecafluoride,** $5TlF.2MnF_3.MnF_2$. It is obtained by precipitating manganese acetate with ammonia and hydrogen peroxide, dissolving the well-washed precipitate in hydrofluoric acid, and adding thallous fluoride, when it forms claret-coloured prisms, decomposed by water, but soluble in cold conc. sulphuric acid or in dilute oxalic or tartaric acids to violet soln., decolorized on heating. When a soln. of manganic fluoride is added to a soln. of cobaltic chloropentamminocarbonate in hydrofluoric acid, O. T. Christensen found that **cobaltic manganese chloropentamminofluoride** is formed as a crystalline precipitate, consisting of microscopic, rectangular plates. O. T. Christensen also prepared **cobaltous manganic pentafluoride,** $CoMnF_5.4H_2O$; and **nickel manganic pentafluoride,** $CoMnF_5.4H_2O$.

According to J. Nicklès,[3] if an ethereal soln. of manganese tetrachloride be treated with hydrofluoric acid, the lower layer of brown liquor is regarded as a soln. of **manganese tetrafluoride,** MnF_4, in hydrofluoric acid; a similar soln. is formed when manganese dioxide is dissolved in hydrofluoric acid; and also by shaking potassium manganese hexafluoride, $2KF.MnF_4$, with a sat. soln. of silicon tetrafluoride in ether. The brown soln. in ether and a little water contains the tetrafluoride, and it is an energetic oxidizing agent. The brown liquid is not decomposed by the addition of a small proportion of water, but is decomposed by a larger proportion, particularly in the presence of alkali hydroxides, carbonates, or chlorides, and finely-divided hydrated manganese dioxide separates. The brown soln. decolorizes indigo, and it is decomposed by ferrous sulphate; an alcoholic soln. of lead acetate gives a brown precipitate; a soln. of brucine is reddened; aniline and naphthylamine furnish coloured derivatives; phenol is oxidized to a brown resin which is coloured green by sodium chloride; while glucose, gum, and carbohydrates are not changed. The soln. dissolves in alcohol; and ether dissolves it only in the presence of a little water. Rose-red double salts are precipitated when potassium or ammonium chloride is added to the brown soln., but sodium chloride gives a precipitate only in the presence of water. O. T. Christensen doubted the existence of the tetrafluoride so prepared. He said that the double salts are not $2RF.MnF_4$, as J. Nicklès supposed, but rather salts of the trifluoride, $2RF.MnF_3.H_2O$; but R. F. Weinland and O. Lauenstein showed that J. Nicklès was probably right. F. Fichter and E. Brunner were unable to oxidize manganous fluoride to manganese tetrafluoride by fluorine, and they added that this is analogous to the failure of E. Müller and P. Koppe to produce this salt by anodic oxidation.

R. F. Weinland and O. Lauenstein showed that potassium manganate dissolves to a violet soln. in 40 per cent. hydrofluoric acid with evolution of heat, and on evaporation the soln. yields a mixture of potassium permanganate and potassium fluomanganite. The **fluomanganites** are here considered to be salts of the hypothetical fluomanganous acid, H_2MnF_6. If potassium manganate be treated with water and carbon dioxide, potassium manganite is formed ; when dissolved in hydrofluoric acid and treated with potassium fluoride, there are deposited golden-yellow hexagonal tablets of **potassium fluomanganite**, K_2MnF_6, or *potassium manganese hexafluoride* :

$$\begin{matrix} KF = F \\ KF = F \end{matrix} Mn \begin{matrix} F \\ F \end{matrix}$$
The hexagonal crystals have the axial ratio $a : c = 1 : 1.6414$. The (0001)-cleavage is incomplete ; the corrosion figures agree with the holohedral symmetry ; the birefringence is feeble and negative. The salt turns reddish-brown when cautiously heated, and recovers its original colour on cooling ; at a higher temp. it volatilizes ; and in contact with moist air yields a violet residue, hydrogen fluoride being evolved ; whilst at a high temp. it is decomposed into oxides of manganese and potassium fluoride. It is decomposed by water, with the precipitation of hydrated manganese dioxide ; it dissolves in cold hydrochloric acid to a dark brown soln. which evolves chlorine when heated ; and when treated with cold, conc. sulphuric acid, it yields hydrofluoric acid, and with the warm acid, oxygen and ozone. With nitric acid it yields manganese nitrate and hydrofluoric acid, and no manganese goes into soln. ; this reaction distinguishes it from O. T. Christensen's complex of manganese trifluoride and potassium fluoride. The salt yields a brownish-red soln. with phosphoric acid ; it is insoluble in glacial acetic acid ; it oxidizes oxalic acid in aq. soln. ; it decolorizes indigo soln. ; and with hydrogen dioxide it yields a reddish residue, with evolution of oxygen. F. Fichter and E. Brunner observed that fluorine immediately reduces the yellow complex salt K_2MnF_6 to the red complex salt $K_2MnF_5.H_2O$. According to R. F. Weinland and O. Lauenstein, **rubidium fluomanganite**, Rb_2MnF_6, is obtained by dissolving hydrated manganese dioxide in hydrofluoric acid and adding rubidium fluoride. It furnishes yellow hexagonal tablets with the axial ratio $a : c = 1 : 1.6185$, and with a feeble negative birefringence. It is quite analogous to the potassium salt. The corresponding **ammonium fluomanganite**, $(NH_4)_2MnF_6$, was obtained contaminated with the potassium salt ; while **sodium fluomanganite**, Na_2MnF_6, could not be prepared.

According to F. Wöhler, when a mixture of two parts of potassium permanganate or manganate and one part of calcium fluoride is digested with sulphuric acid in a platinum retort, a yellow vapour is evolved which in contact with moist air becomes purple. The yellow vapour corrodes glass, and is thereby resolved into silicon tetrafluoride and manganese heptoxide, which covers the glass with a brown layer and dissolves in water forming a purple soln. The yellow vapour attacks calcium chloride, which becomes hot and gives off chlorine. The yellow vapour dissolves in water, forming a soln. of hydrofluoric and permanganic acids. When the aq. soln. is evaporated, it gives off oxygen and hydrogen fluoride, and leaves a brown residue containing some manganous fluoride. The aq. soln. dissolves copper, mercury, and silver, but not gold or platinum. J. B. A. Dumas made some observations on this subject—*vide infra*, manganese tetroxychloride. F. Wöhler's product is sometimes regarded as a *manganese trioxyfluoride*, MnO_3F, but it was probably this mixture of potassium permanganate and fluomanganite contaminated with a silicon fluoride.

In addition to the potassium fluomanganite prepared first by J. Nicklès, *potassium manganese octofluoride*, $4KF.MnF_4$, was reported to be formed by the fusion of the hexafluoride, or by melting a mixture of manganese dioxide and potassium fluoride ; *potassium manganese oxytetrafluoride*, $2KF.MnOF_2$, to be formed as a rose-red precipitate by dropping manganese tetrachloride into a boiling soln. of potassium fluoride ; and *ammonium manganese oxytrifluoride*, $2NH_4F.MnOF$, to be formed by dropping manganese tetrachloride into a hot soln. of ammonium fluoride. If potassium manganese oxytetrafluoride be shaken with ether, sat. with silicon tetrafluoride, a violet-brown acid, $2HF.MnOF_2$, is said to be formed. The soln. is decolorized and decomposed by water. J. Nicklès also reported *potassium dimanganese oxyoctofluoride*, $4KF.Mn_2OF_4$, to be formed by dropping manganese

trichloride in a boiling soln. of potassium fluoride. If hydrofluoric acid be added to potassium permanganate, one or other of these substances is formed and ozonized oxygen is given off. O. T. Christensen could not confirm these observations.

§ 17. Manganous Chloride

J. Davy,[1] and H. Davy reported **manganese dichloride,** or **manganous chloride,** $MnCl_2$, to be formed when manganese burns in chlorine gas. J. L. Proust obtained it by evaporating a soln. of manganous chloride to dryness, and heating the dry residue, according to J. Davy, with the exclusion of air, or, according to E. Turner, in a current of hydrogen chloride. J. A. Arfvedson prepared the anhydrous salt by heating manganous carbonate in a current of hydrogen chloride, first at ordinary temp., and afterwards at a dull red-heat. H. Rose obtained it by passing chlorine over a strongly heated mixture of manganous oxide and charcoal ; and R. Weber used the carbonate in place of the oxide. F. P. Venable and D. H. Jackson obtained the chloride by passing a mixture of carbon monoxide and chlorine over manganese dioxide at 460°.

A. Scacchi observed crystals of manganous chloride in a salt-crust associated with the 1851 eruption of Vesuvius. The crystals were also observed by T. Monticelli and N. Covelli, and M. Adam called the mineral **scacchite**—after A. Scacchi. The crystals of the artificial product are, according to J. A. Arfvedson, rose-red, and they may become dirty red or brown when exposed to air, owing to the formation of higher manganese oxides. There has been some discussion on the

pink colour of the manganous salts generally. C. Fromherz attributed the red colour to the presence of traces of the higher oxidation products. By repeated soln. in sulphuric or hydrochloric acid and reprecipitation with sodium carbonate they obtained a material which furnished colourless manganous chloride or sulphate ; but L. Gmelin said that the red salt cannot be decolorized by boiling with sulphurous acid, or, according to J. J. Berzelius, by treatment with hydrogen sulphide, etc. A. Brand said that colourless crystals can be obtained if the powdered salt be calcined or boiled with alcohol, ether, or a soln. of sugar and again converted into sulphate or chloride. L. Gmelin could not confirm this. F. Brandenburg obtained the red salt by preparing manganous sulphate by the action of fuming sulphuric acid containing a trace of copper on pyrolusite. F. Wöhler, and H. Schiff observed that both colourless and red crystals may be obtained from the same soln. A. Voelcker also found that the purified salt is colourless, and if traces of higher oxides are present, the salt has a reddish tint ; if the tint is not removed by treatment with a reducing agent, the coloration may be due to the presence of a trace of cobalt, which often accompanies manganese. According to J. A. Kappers, and K. J. Bayer, the green or blue tint observed by F. W. Krecke is produced by cobalt ; and A. Gorgeu said that if 8 parts of nickel per 1000 of manganese are present, the salts may be colourless. A. M. B. Burin du Buisson thought that only the anhydrous manganous salts are colourless. The subject was also discussed by J. Schwerdtfeger, and K. Reithner. According to J. H. Kastle, when the crystals of manganous chloride are cooled by liquid air, the colour may disappear altogether ; and A. Étard observed that the rose-red aq. soln. of manganous chloride is almost colourless at 240°.

An aq. soln. of manganous chloride can be prepared by dissolving the metal or manganous carbonate in hydrochloric acid. M. Faraday heated a mixture of precalcined pyrolusite and ammonium chloride slowly to dull redness, and extracted the cold product with water. If the pyrolusite is in excess, it is said that the foreign metals do not form soluble chlorides ; the pyrolusite should have been previously boiled with dil. nitric acid to remove the carbonates of the alkaline earths. J. Everitt evaporated the hydrochloric acid soln. of pyrolusite to dryness, and heated the residue until no more hydrochloric acid is evolved. H. Kolbe recommended heating the residue in a crucible at a red-heat to volatilize the ferric chloride. The residue is dissolved in water and the filtered soln. boiled with manganous carbonate to precipitate the iron and aluminium oxides. K. J. Bayer recommended treating the soln. with sodium carbonate to precipitate fractionally the iron and aluminium oxides, and with ammonium sulphide to precipitate manganous sulphide. The sulphide is then washed and dissolved in hydrochloric acid. The subject was discussed by J. A. Kappers, G. H. Zeller, H. F. Gaultier de Claubry, W. Smith, and A. Pizzi. The evaporation of the aq. soln. furnishes various hydrates, dependent on the conditions.

R. Brandes found that water at 10° can dissolve 38·33 per cent. $MnCl_2$; at 31·25°, 46·15 per cent. ; at 62·5° and at 87·5°, 55·0 per cent. ; and at 106·25°, 55·32 per cent. ; while A. Étard gave for the percentage solubility, S :

	−22°	−·5°	7°	17°	35°	57°	80°	100°	140°
S	34·7	37·8	40·4	41·2	44·4	50·0	51·0	53·7	54·7

The following results for the percentage solubility are compiled from those of F. Rüdorff, A. Ditte, P. Kutznetzoff, R. Brandes, A. Étard, H. M. Dawson and P. Williams, and J. Süss :

	−5·5°	−2°	8°	25°	50°	57·85°	60°	100°	140°
S	10·5	—	38·3	43·6	49·5	51·4	52·1	53·7	54·8
		$6H_2O$		$4H_2O$			$2H_2O$		

The results are plotted in Fig. 59. W. Stortenbeker was able to obtain the **hexahydrate**, $MnCl_2.6H_2O$, only in isomorphous association with hexahydrated cobaltous

chloride, but P. Kutznetzoff showed that a soln. containing 11·7 mols of water per mol of manganous chloride gives the hexahydrate when cooled to —37° and well stirred.   The crystals are almost colourless, and at —2° the hexahydrate passes into the **tetrahydrate**, $MnCl_2.4H_2O$.   The tetrahydrate is dimorphous and appears either as a stable or α-form, or as a labile or β-form.   C. F. Rammelsberg obtained the α-tetrahydrate in rose-red crystals by the spontaneous evaporation of the aq. soln., and by cooling a hot, sat. soln.   The crystals are monoclinic prisms with the axial ratios $a : b : c = 1.1525 : 1 : 0.6445$, and $\beta = 99° 25'$.   The crystals were examined by E. H. Ducloux, and V. C. Butureanu.   According to H. M. Dawson and P. Williams, the transition temp. from the α-tetrahydrate to the dihydrate is 57·85° ;   T. W. Richards and J. B. Churchill gave 57·7° ;   and T. W. Richards and F. Wrede gave 58·089°, and added that this transition temp. is a convenient fixed point for thermometry.   A. Baladin discussed the contraction, and F. Ephraim, the change in vol. accompanying the formation of the salt and of its amines.   J. Süss found that the transition temp. is reduced to 52·8° in the presence of potassium chloride, as shown in Fig. 59.   T. Graham said that the crystals of the tetrahydrate lose two mols. of water in vacuo or over conc. sulphuric acid.   J. F. John added that at 25° the crystals of the α-tetrahydrate become white and opaque ;   and R. Brandes, that between 25° and 37° they give off hygroscopic water with decrepitation and become hard ;   at 37·5° they become tough ;   at 50°, semi-fluid ;   and at 87·5° they form a mobile
FIG. 59.—The Solubility of Manganous Chloride in Water.

liquid which boils at 106°.   If kept for some time at 100°, the α-tetrahydrate loses 3 mols. of water, leaving a white powder.   A. Ditte also found that the α-tetrahydrate at 58° slowly loses water, forming the pale rose-red dihydrate, but does not melt at 120°.   P. Kutznetzoff added that the soln. sat. at 58° can be cooled to 23° before the tetrahydrate begins to separate. E. M. Farrer and S. U. Pickering found that the α-tetrahydrate loses 3 mols. of water at 100°. According to J. C. G. de Marignac, when the aq. soln., sat. at say 40°, is undercooled to 10° or 0°, monoclinic, tabular crystals of β-tetrahydrate separate out.   The crystals were found to have the axial ratios $a : b : c = 1.1413 : 1 : 1.6409$, and $\beta = 110° 46'$.   It was also prepared by P. Kutznetzoff, who observed that at 40° the crystals of the β-tetrahydrate form a crystalline powder of the dihydrate.   J. C. G. de Marignac, H. M. Dawson and P. Williams, and V. C. Butureanu observed that the crystals of the β-tetrahydrate are isomorphous with those of tetrahydrated ferrous chloride.   R. Brandes, and H. M. Dawson and P. Williams said that the β-tetrahydrate melts at 87·6°, and that it is more soluble in water than the α-tetrahydrate.   As just indicated, the transition temp. from the α-tetrahydrate to the **dihydrate**, $MnCl_2.2H_2O$, approximates to 58°.   H. Lescoeur, and A. Ditte prepared the dihydrate by saturating with hydrogen chloride a sat. aq. soln. of the tetrahydrate at 20° ;   and H. M. Dawson and P. Williams, by similarly treating an alcoholic soln. of the tetrahydrate at ordinary temp.   H. Goldschmidt and K. L. Syngros, and H. Lescoeur obtained it by keeping the tetrahydrate in vacuo ; and C. E. Saunders, in attempting to prepare the double salts of lithium or magnesium chloride with manganous chloride, obtained the dihydrate in slender monoclinic prisms with the axial ratios $a : b : c = 1.238 : 1 :$—, and $\beta = 138°$ nearly.   The salt resembles the tetrahydrate, but it does not lose water when dried over calcium chloride.   H. M. Dawson and P. Williams observed that the dihydrate is coloured a deeper red than the tetrahydrate ;   W. Müller-Erzbach, that it loses one of the mols. of water more readily than the other ;   and P. Kutznetzoff, that it loses water at 170°, and when allowed to stand exposed to air for a couple of months, it forms

the tetrahydrate. These results show that there are three well-defined hydrates of manganous chloride, with definite transition temp. :

$$-2° \qquad\qquad 58\,089^{\circ} \qquad\qquad 198^{\circ}$$
$$MnCl_2.6H_2O \rightleftharpoons MnCl_2.4H_2O \rightleftharpoons MnCl_2.2H_2O \rightleftharpoons MnCl_2$$
Some other hydrates have been reported. K. J. Bayer said that the *pentahydrate*, $MnCl_2.5H_2O$, is formed in deliquescent, monoclinic crystals by the evaporation of an aq. soln. of manganous chloride at ordinary temp. ; but at 0°, R. Brandes always obtained the tetrahydrate. P. Sabatier also reported that when the higher hydrates are allowed to stand for some months at a summer temp. in vacuo over sulphuric acid, the *tritapentahydrate*, $MnCl_2.1\frac{1}{4}H_2O$, is formed, but H. M. Dawson and P. Williams could not confirm this observation. A. Ditte obtained crystals of a *monohydrate*, $MnCl_2.H_2O$—perhaps a misprint for the dihydrate—from a soln. of the salt in conc. hydrochloric acid—*vide infra*, E. M. Farrar and S. U. Pickering, W. Müller-Erzbach, and R. Brandes on the action of heat on the di- or tetrahydrate. The hydrates existing in aq. soln. have been discussed by H. C. Jones and co-workers.

. According to E. M. Farrer and S. U. Pickering, when the tetrahydrate is heated at 200° to 230°, it loses some chlorine, while retaining a mol. of water ; and F. W. Krecke also found that the tetrahydrate loses hydrogen chloride, forming a basic chloride when heated. H. M. Dawson and P. Williams observed that the dihydrate loses its water of hydration at 198°, forming the anhydrous salt. A. Hantzsch and H. Carlsohn discussed the nature of the manganese halides. According to G. Bruni and A. Ferrari, the X-radiograms of crystals of anhydrous manganous chloride show a rhombohedral space-lattice with the axial ratio $a : c = 1 : 2.34$; and A. Ferrari and co-workers gave $a = 7.350$ A., $c = 17.45$ A., and $a : c = 1 : 2.37$. They also examined isomorphous mixtures with ferrous and cobaltous chlorides, and L. Pauling made observations on the subject. W. Klemm discussed the energy of the crystal lattice. The crystals of scacchite were observed by A. Lacroix, A. Scacchi, L. Pauling, and T. Monticelli and N. Covelli. According to H. G. F. Schröder, the **specific gravity** of the anhydrous salt is 2.478 ; A. Ferrari and co-workers calculated 3.069 from the X-radiograms. For the sp. gr. of the a-tetrahydrate J. F. John gave 1.56 ; C. H. D. Bödeker, 2.01 at 10° ; H. G. F. Schröder, 1.898 to 1.928 ; and G. P. Baxter and M. A. Hines, 2.977 at 25°/4°. F. Ephraim and A. Schütz, and W. Klemm discussed the molecular volume. G. T. Gerlach gave for the sp. gr. of aq. soln. of p per cent. of $MnCl_2$ at 15°/15° :

p	5	10	15	20	25	30	35	40	45
Sp. gr.	1.045	1.091	1.138	1.189	1.245	1.306	1.372	1.443	1.514

and H. M. Dawson and P. Williams gave for the sp. gr. of soln. sat. at $\theta°$, and containing S mols of $MnCl_2$ per 100 mols of water :

	25°	30°	40°	50°	57.65°	60°	70°	80°
S	11.05	11.55	12.69	14.05	15.10	15.55	15.84	16.14
Sp. gr.	1.4991	1.5049	1.5348	1.5744	1.6097	1.6108	1.6134	—

Observations on the sp. gr. of aq. soln. were also made by J. H. Long, W. Biltz, G Quincke, J. Wagner, H. C. Jones and F. H. Getman, and H. C. Jones and H. P. Bassett ; for those of A. Heydweiller, *vide infra*. B. Cabrera and co-workers gave for the concentration, C grms. of anhydrous salt per 1000 grms. of water, with soln. of sp. gr. D, $C = 2.60 + 1146(D_{20} - 1) - 574.2(D_{20} - 1)^2$; and for soln. with $C = 384.2$, $D = 1.4257\{1 - 0.00031(\theta - 20)\}$; for $C = 277.0$, $D = 1.2784\{1 - 0.00027 \times (\theta - 20)\}$; for $C = 156.6$, $D = 1.1437\{1 - 0.00022(\theta - 20)\}$; for $C = 82.22$, $D = 1.0724 \times \{1 - 0.0019(\theta - 20)\}$; for $C = 53.74$, $D = 1.0454\{1 - 0.00018(\theta - 20)\}$; for $C = 34.89$, $D = 1.0286\{1 - 0.0017(\theta - 20)\}$; and for $C = 15.66$, $D = 1.0120\{1 - 0.00015(\theta - 20) - 0.0_68(\theta - 20)^2\}$. According to I. Traube, the mol. **solution volumes** of the salt in 5, 20, and 40 per cent. soln. at 15°/15° are respectively 17.4, 25.8, and 29.1. A. N. Campbell examined the thesis that the sp. gr. of salt soln. can be calculated from the equation $D_N = D'_N + N(m_a + m_b)$, where D_N is the sp. gr. of the soln. with

N eq. of the salt per litre, D'_N the sp. gr. of a soln. of ammonium chloride of the same normality, and m_a and m_b are moduli for the salt in question. I. I. Saslawsky examined the relative contraction which occurs in the formation of the chloride from its elements. The **electrostriction** is the contraction in the mol. vol. of the salt on soln., that is, mol. vol. of the solid salt less its mol. vol. in soln., and it was discussed by P. Drude and W. Nernst, V. Polowzoff, F. Kohlrausch, A. B. Lamb and R. E. Lee, and G. P. Baxter and C. C. Wallace. The true soln. vol. is supposed to be represented by $M(\mu^2-1)/D(\mu^2+2)$, where μ is the refractive index for light of infinite wave-length.

Eq. per litre	0·5	0·3	0·2	0·1	0·05	0·02	0·01
Sp. gr. 15°/15°	1·02599	1·01587	1·01033	1·00507	1·00240	1·00094	1·00047
$m_{\frac{1}{2}mn} \times 10^4$	354	355	343·5	338	290	300·5	280
Electrostriction	20·4	22·3	19·75	17·85	12·45	10·8	10·45

Analyses of the anhydrous salt by R. Brandes, J. Davy, J. A. Arfvedson, and E. Turner agree with the formula $MnCl_2$; and of the tetrahydrate, by R. Brandes, T. Graham, C. F. Rammelsberg, J. C. G. de Marignac, and G. P. Baxter and M. A. Hines, with $MnCl_2,4H_2O$. The **vapour density** of the anhydrous salt, determined by J. Dewar and A. Scott, 135, is in agreement with the theoretical value, 126, for $MnCl_2$. N. Castoro calculated a **molecular weight** of 131·3 to 141·2—theoretical 126—from the f.p. of soln. of the anhydrous chloride in urethane ; and L. Rügheimer and co-workers, 129·8 from the b.p. of soln. in bismuth trichloride. G. Bruni and A. Manuelli inferred from the effect of the tetrahydrate on the f.p. of acetamide that a part of the water of crystallization remains bound to the $MnCl_2$, while with soln. in acetamide all the water separates from the $MnCl_2$.

S. Motylewsky observed that the **drop weight** of molten anhydrous chloride at its m.p. is 103 when that of a drop of water at 100° is 100. C. A. Valson found that the **capillary rise** of a normal soln. at 13° is 58·5 mm. in a tube 0·5 mm. diameter. M. Goldstein found that the capillary rise of a 17·776 per cent. soln. at 15·5° is 143·44 when that of water is 154·5. L. C. de Coppet, and F. Dreyer discussed the capillarity, and G. Tammann, the inner pressure of the soln. H. Sentis found for temp. between 16·9° and 18·4° the **surface tension, δ** dynes per cm., and the **specific cohesion,** a^2 per sq. mm., for aq. soln. with p per cent. $MnCl_2$:

p	6·60	12·49	17·76	22·56	26·90	30·85	34·42	37·81
δ	75·08	76·78	78·30	80·26	82·13	83·66	85·22	87·48
a_2	14·51	14·15	13·80	13·56	13·34	13·11	12·90	12·80

Observations on the surface tension were also made by W. H. Whatmough, and H. Piepenstock. J. C. Graham measured the rate of **diffusion** of manganous chloride in aq. soln. ; and for the **viscosity** at 25°, water unity, of N-, $0·5N$-, $0·25N$-, and $0·125N$-soln. J. Wagner observed respectively 1·2089, 1·0982, 1·0481, and 1·0230, when the respective sp. gr. are 1·0513, 1·0259, 1·0125, and 1·0063. H. C. Jones and W. R. Veazey made some observations on this subject.

J. C. G. de Marignac observed that the **specific heats** of soln. of a mol of manganous chloride in 50, 100, and 206 mols of water between 19° and 52° are respectively 0·8510, 0·9154, and 0·9526 ; and for 30 and 50 per cent. soln. between 0° and 98° A. Blümcke found the sp. hts. to be respectively 0·733 and 0·608. The subject was discussed by N. de Kolossowsky, and K. Jauch. C. Sandonnini, and A. Ferrari and A. Inganni found the **melting-point** of the anhydrous chloride to be 650°, without decomposition ; and it volatilizes at a higher temp. in a current of hydrogen chloride. A. Ferrari discussed some relations of the m.p. C. R. A. Wright and A. E. Menke found that **volatilization** occurs at a red-heat. As indicated above, R. Brandes, and H. M. Dawson and P. Williams found the m.p. of the tetrahydrate to be 87·6° ; J. B. A. Dumas made some observations on this subject. E. N. Gapon studied some relationships of the m.p. F. Rüdorff found that the **freezing-point** of aq. soln. falls 0·138° for a gram of the salt in 100 grms. of water, and it thus falls proportionally with the proportion of salt in soln. Observations

were also made by L. C. de Coppet, and H. Goldschmidt and K. L. Syngros. For soln. with M mols of the salt per litre, H. C. Jones and F. H. Getman, and H. C. Jones and H. P. Bassett found **the lowering of the freezing-point** of water, $\delta\theta$, and the mol. lowering, $\varDelta$, to be :

M .	.	0·053	0·106	0·400	1·061	2·00	3·00	4·00
$\delta\theta$.	.	0·255°	0·508°	2·004°	5·965°	16·500°	31·000°	48·500°
$\varDelta$.	.	4·81	4·79	5·01	5·62	8·25	10·33	12·13

R. Salvadori, and W. Biltz made observations on this subject ; for the observations of N. Castoro, and of G. Bruni and A. Manuelli, *vide supra*. R. Salvadori found **the raising of the boiling-point** of soln. with 1·31, 3·69, and 12·89 grms. of $MnCl_2$ in 100 grms. of water to be respectively 0·12°, 0·39°, and 1·43°, and the corresponding mol. lowering to be 1·1, 1·3, and 1·4. According to C. G. Maier, the **vapour pressure,** p atm., of the anhydrous salt is :

		785·4°	882·1°	934·0°	1017·4°	1096·0°	1149·0°	1190·4°
p .	.	0·01	0·05	0·10	0·25	0·50	0·75	1·00
Q .	.	—	38·30	36·02	32·52	30·61	29·58	28·78

K. Jellinek and R. Ulroth obtained for $MnCl_2+H_2 \rightleftharpoons Mn+2HCl$ at 700°, p_{HCl}/p_{H_2} $=2·02\times10^{-3}$, and, by extrapolation at 0°, $2·08\times10^{-3}$. According to G. Tammann, the **lowerings of the vapour pressure** of soln. of 8·83, 15·85, 44·45, and 66·03 grms. $MnCl_2$ in 100 grms. of water are respectively 21·9, 44·0, 147·9, and 219·0 mm. H. M. Dawson and P. Williams found the vap. press., p mm., of a sat. soln. with a solid phase of the tetrahydrate at temp. below 57·8°, and of the dihydrate above that temp. ; the **dissociation pressure,** p_4 mm., of the tetrahydrate : $MnCl_2.4H_2O$ $\rightleftharpoons MnCl_2.2H_2O+2H_2O$; and the dissociation press., p_2 mm., of the dihydrate : $MnCl_2.2H_2O \rightleftharpoons MnCl_2+2H_2O$, to be :

	15·5°	20·0°	30·0°	40·0°	50·0°	57·8°	60·0°	70·5°	80·5°	90·0°
p .	7·85	9·45	17·02	28·67	46·29	62·9	64·8	110·25	172·1	262·0
p_4 .	3·50	4·06	9·31	19·28	41·72	62·83	—	—	— ·	—
p_2 .	—	—	— ·	2·9	5·9	—	13·8	26·0	38·4	73·2

H. Lescoeur also made some observations on the dissociation press. of these hydrates. C. G. Maier's values for the **heat of vaporization** of the anhydrous salt, Q cals. per mol, are indicated above. According to J. Thomsen, the **heat of formation** $(Mn,Cl_2)=112$ Cals., and, according to M. Berthelot, 112·6 Cals. M. Berthelot gave $(Mn,Cl_2,Aq.)=128·6$ Cals. ; and J. Thomsen, $(Mn,2HCl_{aq.})=49·4$ Cals., and M. Berthelot, 49·8 Cals. J. Thomsen gave $(MnCl_2,4H_2O)=14·47$ Cals. For the **heat of neutralization** J. Thomsen gave $Mn(OH)_2+2HCl_{aq.}=MnCl_{2aq.}+22·95$ Cals., and M. Berthelot, 23·7 Cals. ; M. Berthelot gave $MnCl_{2aq.}+2NaOH_{aq.}$ $=Mn(OH)_2+2NaCl_{aq.}+3·7$ Cals. ; and for the **heat of solution,** $(MnCl_2,Aq.)=16·01$ Cals. J. Thomsen gave for the heat of soln. of the tetrahydrate 1·54 Cals. ; and P. Sabatier gave for that of $MnCl_2.1\tfrac{2}{3}H_2O$, 9·1 Cals. at 21°. J. Perreu gave $-4·56$ Cals. for the limiting heat of soln. of the tetrahydrate. G. Beck studied the energy of formation. W. Herz discussed the entropy and vibration frequency ; and G. Beck, the free energy of formation of the salt ; G. Devoto and A. Guzzi gave for the free energy of formation :

	700°	750°	800°	850°	900°	950°
Free energy .	87,150	86,440	83,210	81,050	76,230	72,000 cals.

According to H. C. Jones and F. H. Getman, the **indices of refraction,** μ, of soln. with M mols of manganous chloride per litre, for the D-line, are :

M .	.	0·053	0·106	0·133	0·266	0·533	0·796	0·902
μ .	.	1·32656	1·32766	1·32829	1·33150	1·33768	1·34363	1·34588

A. N. Campbell considers that these results are affected by a constant error, because

they are less than the result for water alone, viz. 1·33113 for μ_C and 1·33713 for μ_F; and he obtained :

Eq. per litre	0·5	0·3	0·2	0·1	0·05	0·02	0·01	0·005
μ_C	1·33636	1·33437	1·33327	1·33228	1·33196	1·33163	1·33147	1·33131
μ_F	1·34239	1·34044	1·33918	1·33822	1·33785	1·33756	1·33742	1·33727

These results agree with $\mu_C=1·96$ and $\mu_C=2·00$ for the solid chloride. C. J. W. Grieveson measured the absorption spectrum. The **flame spectrum** was described by R. T. Simmler, G. Hüfner, and J. Müller; and C. Sheard and C. S. Morris found a continuous region in the emission spectrum of manganous chloride between 5900 and 4450 A. C. J. W. Grieveson, J. von Koczkes, and S. Kato studied the absorption spectrum of dil. soln. The specific **electromagnetic rotation** of the plane of polarization was found by R. Wachsmuth to be 1·0434, and the mol. rotation, 7·3037. L. R. Ingersoll gave for Verdet's constants in angle minutes for light of wave-lengths 0·6, 0·8, 1·0, and 1·5μ respectively 0·0141, 0·0078, 0·0054, and 0·0034 for a soln. of manganous chloride of sp. gr. 1·326. H. Jahn, and G. Quincke made some observations on this subject. D. M. Yost found that the K-absorption discontinuities are the same for manganous ions in soln. or in the solid state. L. de Boisbaudran, J. R. Mourelo, and V. Klatt and P. Lenard discussed the **phosphorescence** produced by the presence of manganous salts in the oxides of various metals. R. Robl observed no fluorescence in ultra-violet light. O. Gossmann found that no ions are emitted by the salt heated below 425°. O. Stelling, D. M. Yost, S. Aoyama and co-workers, and K. Fajans studied the **X-ray absorption**; P. Krishnamurti, the **Raman effect**; and F. Allison and E. J. Murphy, the **magneto-optic effects.**

W. Hampe observed that molten manganous chloride is a good electrical conductor. The **electrical conductivity**, λ mhos, of aq. soln. of manganous chloride measured by J. H. Long for soln. with $\bar{p}$ per cent. of $MnCl_2$, at 18°, furnished :

p	5	10	15	20	25	28
λ	63·3	48·8	38·9	30·0	22·0	17·8

and for more dil. soln. H. Ley gave for soln. with a mol of $MnCl_2$ in v litres, at 25° :

v	32	64	128	256	512	1024
λ	100·4	104·4	108·8	111·6	115·2	118·9

A. Heydweiller gave for the sp. gr. and eq. electrical conductivity, at 18° :

	0·5N-	N-	2N-	3N-	4N-	5N-	6N-
Sp. gr.	1·02589	1·0512	1·1010	1·1496	1·1975	1·2448	1·2917
λ	66·4	57·4	45·27	(35·7)	28·17	(21·8)	16·30

H. C. Jones and F. H. Getman, H. C. Jones and H. P. Bassett, and W. Althammer measured the mol. conductivity, μ, and H. C. Jones and A. P. West also calculated the degree of ionization, α, for temp. between 0° and 65° :

v		2	8	16	32	128	512	1024
	0°	68·14	84·98	91·79	97·4	107·0	114·1	114·9
μ	25°	121·3	156·7	169·0	181·6	202·5	216·6	216·8
	50°	—	218·0	—	288·5	329·0	357·6	374·3
	65°	—	297·9	—	355·0	406·8	444·7	465·8
	0°	59·3	74·0	79·0	84·8	93·1	99·3	100·0
α	25°	56·0	72·3	78·0	83·8	93·4	99·9	100·0
	50°	—	58·2	—	77·1	87·9	95·5	100·0
	65°	—	63·9	—	76·2	87·3	95·5	100·0

The values for the **degree of ionization** are indefinite because of the lack of a criterion to distinguish whether or not the ionization occurs in stages $MnCl_2 \rightleftharpoons MnCl'+Cl'$ and $MnCl' \rightleftharpoons Mn''+Cl'$. There is no minimum in the conductivity or refractivity curves corresponding with the minimum observed by H. C. Jones and F. H. Getman in the f.p. curves. The phenomenon is explained by the assumption of H. C. Jones

and V. J. Chambers that in conc. soln. the dissolved substance combines with the solvent with formation of hydrates, which exist in the soln. together with a small proportion of ions resulting from the electrolytic ionization of the salt, and that those substances which yield crystals containing the largest amount of water of crystallization would be expected to form the most complex hydrates in soln. The subject was discussed by W. Biltz, H. C. Jones, and A. Günther-Schulze. W. Bein calculated the **transport number** for the cations of $0.05N$-$MnCl_2$ to be 0.387 at $18°$. E. Rimbach and K. Weitzel measured the conductivity, λ, in methyl and ethyl alcohols, and in acetone, at temp. $\theta°$, between $0°$ and $45°$. The results are represented as a function of the temp. by $\lambda = \lambda_{1.5°}\{1 + a(\theta - 7.5) + b(\theta - 7.5)^2\}$, for an eq. of the salt in v litres, where a and b are constants with the following values :

CH_3OH	v	2.451	9.832	35.79	143.2	576.1
	$\lambda\,7.5°$	12.33	19.07	26.67	35.28	47.23
	a	1.23	1.19	1.16	1.05	1.05
	b	−3.5	−1.67	0.52	1.01	−2.25
C_2H_5OH	v	1.658	9.324	37.30	55.88	223.5
	$\lambda\,7.5°$	2.389	3.263	5.301	6.085	8.948
	a	1.24	1.27	1.47	1.45	1.51
	b	−8.5	−11.2	−13.5	−10	−4.1
$CH_3CO.CH_3$	v	76.91	153.8	207.6	615.3	1231
	$\lambda\,7.5°$	9.521	10.68	11.61	12.24	12.76
	a	0.663	0.548	0.508	0.451	0.404
	b	−4.79	−10.3	−9.36	−8.48	−7.75

Observations were made by E. C. Banks and co-workers. R. Müller and co-workers observed that $0.1N$- and $0.168N$-soln. of manganous chloride at $25°$ show indefinite **decomposition potentials** of about 2 volts. G. Devoto studied the subject. The **electrolytic oxidation** of manganous salts has been discussed by N. W. Fischer, A. C. Becquerel, C. Luckow, M. Berthelot, A. Classen, A. Classen and M. A. von Reis, F. Rüdorff, A. Riche, A. Brand, L. Schucht, C. Engels, J. Köster, A. Piccini, E. Frei, K. Elbs, Badische Anilin- und Sodafabrik, F. W. Skirrow, M. G. Levi and F. Ageno, C. N. Otin, E. Grave, and G. D. van Arsdale and C. G. Maier—*vide supra*, manganese dioxide and the permanganates. M. Sem said that the electrolytic oxidation at $10°$ proceeds only to the manganic stage, and at $60°$ there is no sign of the formation of a tetrachloride. B. Neumann found the e.m.f. of the cell $Mn_nHg \mid 0.5N$-$MnCl_2 \mid$ electrolyte $\mid N$-$KCl,Hg_2Cl_2 \mid Hg$ to be -1.384 volts at room temp.—*vide supra*, the potential of manganese.

P. Théodoridès gave 110.95×10^{-6} mass unit for the **magnetic susceptibility** of the solid chloride. G. Wiedemann, and E. Wedekind said that the magnetic susceptibility of soln. of the manganous salts is greater than that of the ferric salts. The subject was studied by A. Duperior, B. Cabrera and co-workers, F. Auerbach, O. Wylach, G. Piaggesi, G. Quincke, G. Jäger and S. Meyer, A. Heydweiller, and P. Pascal. O. Liebknecht and A. P. Wills gave 117×10^{-6} to 127×10^{-6} mass unit at $18°$; T. Ishiwara, 111.8×10^{-6} ; P. Théodoridès, 114.8×10^{-6} ; and W. Sucksmith, 112.2×10^{-6} ; B. Cabrera and A. Duperior, G. Falckenberg, and P. Théodoridès studied the effect of temp. on the susceptibility. T. Ishiwara, and K. Honda and T. Ishiwara gave :

	$-178.9°$	$-58.7°$	$-22.0°$	$23.9°$	$119.7°$	$328.4°$	$428.6°$	$621.0°$	$717.4°$
$\chi \times 10^6$	393.0	152.5	129.7	107.0	78.6	51.3	43.2	33.5	28.0

W. L. Rolton and R. S. Troop observed no change in the surface tension of soln. of the salt under the influence of a magnetic field of 16,000 gauss ; and W. E. Garner and D. N. Jackson, no change on the mutarotation of sugar by manganous chloride in a magnetic field. S. S. Bhatnagar and co-workers observed that paramagnetic manganese salts become diamagnetic when adsorbed on charcoal, showing that adsorption is more analogous with chemical combination than admixture. G. Quincke found the magnetic susceptibility of aq. soln. to be :

Sp. gr.	1.0357	1.1209	1.1739	1.2992	1.3339	1.3695
Susceptibility $\times 10^6$	5.86	19.5	28.3	49.8	56.1	58.3

and he gave 34.8×10^{-6} for a soln. in methyl alcohol of sp. gr. 1.0800 ; and for soln. in ethyl alcohol of sp. gr. 1.0258 and 1.0304 respectively 30.2×10^{-6} and 30.6×10^{-6}. B. Cabrera and A. Duperior, and J. Aharoni studied the magnetism of aq. soln., and they gave for soln. with C grms. of anhydrous salt per 1000 grms. of solvent, $C=0.3845$, the mol. susceptibility is 0.0150, and for $C=0.00582$ the mol. susceptibility is 0.149. These results agree with $4.4=X(T+\Theta)$. S. Freed and C. Kasper discussed the susceptibility of manganous ions involved in the formation of complex salts. G. Jäger and S. Meyer gave 52.4×10^{-6} for an aq. soln. with 3.55 mols per litre ; and H. du Bois, for an aq. soln. of sp. gr. 1.045, 6.82×10^{-6}. Water alone is diamagnetic, and paramagnetic if the sp. gr. exceeds this value :

Sp. gr.	0.9992	1.0010	1.0028	1.0040	1.0054	1.0087	1.0445
Susceptibility $\times 10^6$	-0.837	-0.418	-0.127	0.000	0.182	0.578	0.819

J. A. Arfvedson, and J. J. Ebelmen found that manganous chloride is not decomposed by **hydrogen** at a red-heat. K. Jellinek and co-workers studied the reduction potential of the chloride by hydrogen. W. Ipatieff and W. Kisseleff observed that hydrogen at 300° and over 150 atm. press. acts on soln. of manganous chloride, forming $MnO.H_2O$. K. Jellinek and R. Ulroth studied the reaction $MnCl_2+H_2 \rightleftharpoons 2HCl+Mn$ at elevated temp. M. Berthelot observed that when the chloride is heated in **oxygen,** the higher manganese oxides are formed. According to J. Meyer and R. Nerlich, manganous ions are not oxidized by atm. oxygen ; nor has the presence of sodium sulphite or arsenite any influence. Manganous salts in ammoniacal or alkaline soln. are oxidized to manganic hydroxide ; thus, manganous chloride made alkaline with ammonia and mixed with ammonium chloride is oxidized by air to manganic hydroxide. In the presence of tartaric or oxalic acid, manganous salts are not precipitated by alkalies, and autoxidation takes place rapidly. In the presence of ammonia, the product is manganic hydroxide, but in the presence of sodium or potassium hydroxide, manganese dioxide is formed, probably because in presence of these stronger alkalies the complex compound is less stable, some manganous hydroxide being always present and oxidizing directly to the dioxide. Potassium and sodium manganocyanides were oxidized to manganic hydroxide, whilst soln. of a manganous salt mixed with potassium thiocyanate were not oxidized at all. V. Lenher found that when a 1 per cent. soln. of manganous chloride and about a gram of calcite were kept for a few weeks in the presence of lead, bismuth, tin, arsenic, antimony, mercury, copper, zinc, nickel, cobalt, cadmium, silver, gold, mercuric sulphide, millerite, pyrites, chalcopyrite, and zinc-blende, the first noticeable separation in the tube with the soln. and calcite alone occurred after several weeks. Lead and bismuth accelerate the reaction, producing the same effect in a few hours. All the other substances had no accelerating effect. In fact, in the case of antimony, tin, and arsenic there was a retarding action, but this was due, not to a negative catalysis, but to the reducing action of the salts of these metals which would be formed. J. Davy observed that when heated to redness in **air,** manganosic oxide is formed, while L. Gmelin added that no free chlorine is evolved, and A. Gorgeu, that an *oxychloride,* $MnCl_2.2Mn_2O_3$ is first formed ; this passes into hemitrioxide, and at a higher temp. a higher oxide is formed. I. F. Hoffmann studied the catalytic oxidation of manganous salts with tetramethyl-p-phenylenediamine as catalytic agent. W. Weldon found that when a mixture of manganous and magnesium chlorides is heated in a current of air, chlorine and magnesium manganite are formed. Manganous ions do not oxidize in acidic or neutral soln., but, as shown by J. Meyer and co-workers, soln. containing hydroxyl-ions yield hydrated manganese hemitrioxide or dioxide —*vide supra,* manganous hydroxide. C. F. Schönbein observed that paper soaked with a manganous salt becomes brown when exposed to **ozone ;** and P. Jannasch and W. Gottschalk, that a soln. of a manganous salt when treated with ozone precipitates hydrated manganese dioxide. A. Mailfert observed that there are

three kinds of products : (i) conc. soln. give a brown or black precipitate of manganese dioxide provided the ozone is in excess ; (ii) a violet soln. of permanganate in soln. with a dilution not exceeding 1 : 3000 ; and (iii) a yellow or brown soln. with a dilution of from 1 : 30,000 to 1 : 600,000, and the composition of the product is Mn_3O_8 or Mn_4O_{11}. According to L. Maquenne, the precipitation by ozone must be regarded as the result of a secondary reaction between an untransformed portion of the salt and the permanganate produced by immediate oxidation. If more than 10 per cent. of sulphuric acid is present, the hydrated dioxide is no longer precipitated, and if over 30 per cent. is present, manganic sulphate is formed instead of permanganate. In very conc. soln. of manganese, precipitates are always formed; at least 50 per cent. of sulphuric acid is present; if otherwise manganic sulphate is produced.

F. Kuhlmann found that when the chloride is heated in **water** vapour, hydrogen chloride and manganese tritatetroxide are produced. The solvent action of water has been previously described. The taste of the salt is described by J. L. Proust as being saline, but not unpleasant. L. Bruner found the **hydrolysis** of soln. of manganous chloride to be too small for measurement. According to H. W. Fischer, the salt is hydrolyzed when an aq. soln. is heated to 200° in a bomb, and a dark brown precipitate is formed. A. Gorgeu observed that when an excess of a hot, conc. soln. of manganous chloride is treated with sodium carbonate and boiled half an hour, a gelatinous precipitate of the *oxychloride* $MnCl_2.2$ or $3MnO$ is formed ; and if manganous chloride be melted at a dark red-heat in the presence of steam, but with the exclusion of oxidizing gases, **manganous oxydichloride**, Mn_2OCl_2, is formed in acicular crystals which are slowly decomposed by water and alcohol. A. F. Rogers described emerald-green crystals of a manganese oxychloride, or **manganese dichlorotripermanganite**, $MnCl_2.3MnO_2.3H_2O$, or $Mn_4Cl_2O_6.3H_2O$, from the vicinity of San José, California, and the mineral was called **kempite**—after J. F. Kemp. The rhombic crystals have the axial ratios $a : b : c = 0.677 : 1 : 0.747$; the sp. gr. is 2·94 ; the hardness, 3·5 ; and the indices of refraction $\alpha = 1.684$, $\beta = 1.695$, and $\gamma = 1.698$. Kempite dissolves in hydrochloric acid with the evolution of chlorine.

According to G. Rosenthal, **hydrogen dioxide** precipitates manganese dioxide from an acetic acid soln. of a manganous salt. The reaction was studied by S. T. Orlowsky. B. C. Brodie found that in alkaline soln. hydrogen dioxide oxidizes the manganous salt to the dioxide. A. C. Robertson examined the catalytic decomposition of hydrogen dioxide by the manganous salts. For the action on permanganate, *vide supra*. S. T. Orlowsky studied the action of **sodium dioxide.** H. Kwasnick found that **barium dioxide** in a soln. of a manganous salt gives off oxygen vigorously ; the action of **lead dioxide** has been discussed in connection with the formation of permanganic acid. O. Kühling found that manganous salt soln. are slowly oxidized by **silver peroxide** and nitric acid in the cold; a permanganate is first formed, and the soln. then becomes colourless owing to the separation of hydrated manganese dioxide. If more silver peroxide is added, the pink colour does not disappear until the soln. is heated, and finally the colour is persistent and a clear soln. of permanganate is formed.

According to H. Moissan, **fluorine** transforms manganous chloride largely into the trifluoride. V. Thomas and P. Dupuis observed that liquid **chlorine** at its b.p. does not act on manganese chloride. N. A. E. Millon observed that chlorine oxidized dil. soln. of manganese chloride to the hydrated dioxide, and A. Sobrero and F. Selmi observed a similar result occurs in darkness in the presence of alkali or alkaline earth chloride. As shown by L. F. Rivot and co-workers, F. Stromeyer, J. Schiel, H. Rose, C. R. Fresenius, and J. Volhard, chlorine oxidizes hot, dil. neutral or feebly acidic soln. of manganous salts to hydrated manganese dioxide, and even to permanganate—*vide supra* ; and H. Kämmerer, T. T. Morrell, E. Riley, S. T. Orlowsky, and P. Waage obtained similar results with **bromine**. R. F. Weinland and F. Schlegelmilch found that orange-red needles of **manganous diiodocto-**

chloride, $MnCl_2.2ICl_3.8H_2O$, are formed by passing chlorine into a suspension of **iodine** in a conc. soln. of manganous chloride. As in the case of other bivalent salts, there is a general tendency of the manganous salts to form complex anions with a feeble electro-affinity. S. T. Orlowsky studied the oxidizing action of iodine. K. Fredenhagen and G. Cadenbach, and K. Fredenhagen studied the action of **hydrofluoric acid** on manganous chloride. B. E. Dixon and J. L. White, T. J. Pearsall, E. and B. Klimenko, J. Volhard, and R. Phillips showed that a soln. of a manganous salt is oxidized by **sodium or calcium hypochlorite**—*vide supra*, potassium permanganate; E. Dèniges, by **sodium hypobromite**; and the action was found by A. J. Balard, and J. Pelouze to be very slow with **chloric acid.** C. F. Rammelsberg, and S. R. Benedict also found that manganous salts are oxidized by **bromic acid,** and **periodic acid.** W. Ostwald observed that manganous chloride exerts a small catalytic action on the velocity of the reaction between bromic and hydriodic acids. N. Isgarischeff and S. Schapiro observed its effect on the rate of dissolution of marble. J. F. Simon, and D. Vitali found that manganous salts are oxidized by **potassium bromate** and sulphuric acid; J. F. Simon, by hot soln., by **potassium chlorate** and sulphuric acid; and J. B. Hannay, by potassium chlorate and nitric acid. According to J. Townsend, chlorine is formed when bricks soaked in manganous chloride are heated to $100°$–$150°$ in a current of **hydrogen chloride** and air; and M. G. Levi and V. Bettoni studied the action of manganous chloride as a catalytic agent in H. W. Deacon's process for chlorine. M. Berthelot observed that fuming **hydrochloric acid** and oxygen added to a soln. of manganous chloride at ordinary temp. form chlorine. A. Ditte found that the solubility of manganous chloride in hydrochloric acid increases with increasing proportions of HCl; it is greater with hot than with cold soln.; he also added that the monohydrate crystallizes from cold soln. in the conc. acid—100 c.c. of the conc. acid dissolves 19 grms. of the salt at $12°$. M. Bobtelsky studied the catalytic effect of manganous chloride on the oxidation of hydrochloric acid by chromic acid; and M. Bobtelsky and A. Rosenberg, the catalytic effect of Mn ·-ions on the oxidation of **hydrogen bromide** by chromic acid.

H. A. von Vogel observed that when manganous chloride is heated with **sulphur,** manganous sulphide is formed. A. W. Ralston and J. A. Wilkinson found that the soln. in liquid **hydrogen sulphide** is non-conducting. In the equilibrium $MnCl_2+H_2S \rightleftharpoons MnS+2HCl$, K. Jellinek and G. von Podjasky found that equilibrium occurs at $407°$ with 15 per cent. HCl by vol.; at $506°$ with 43·5 per cent. HCl by vol.; and at $583°$ with 72 per cent. HCl by vol.; and he gave for the heat of the reaction $-26·030$ Cals. O. Ruff and B. Hirsch discussed the fractional precipitation of manganese as sulphide, hydroxide, and carbonate. According to H. W. F. Wackenroder, hydrogen sulphide gives no precipitate with neutral or acidic soln. of manganous salts, but with neutral acetate a little manganous sulphide may be formed. A soln. of **ammonium sulphide** gives a flesh-coloured precipitate of manganous sulphide, which is oxidized brownish-black on exposure to air, and which is insoluble in an excess of the precipitant, but soluble in dil. acids. J. Lefort and P. Thibault said that the precipitation of the sulphide is hindered by the presence of gum arabic; J. Spiller, by the presence of alkali citrates; and H. Rose, by the presence of pyrophosphates. The subject was discussed by A. Classen, H. How, C. R. Fresenius, and A. Terreil. A soln. of a manganous salt is not affected by **sulphur dioxide.** P. Berthier also said that **potassium sulphide** gives a precipitate when the soln. is boiled, but not so with **ammonium sulphite.** L. Meyer observed that the oxidation of sulphurous acid in air is accelerated by manganese salts more than is the case with ferrous, cobalt, nickel, zinc, cadmium, or magnesium salts. L. Meyer found it to be a good catalyst in the oxidation of sulphur dioxide. A. Vogel found that with cold, conc. **sulphuric acid** hydrogen chloride is evolved and manganous sulphate is formed. The action of **persulphates** has been discussed in connection with the formation of permanganic acid. O. W. Gibbs observed no

precipitation when a manganous salt soln. is heated with **sodium thiosulphate** under press., but J. T. Norton found that a little manganous sulphide is formed. O. Brunck observed no action with **sodium hyposulphite.**

E. P. Lewis observed no phosphorescence with active **nitrogen.** G. Gore, and E. C. Franklin and C. A. Kraus stated that manganous chloride is insoluble in liquid **ammonia.** H. N. Warren noted that when the chloride is heated with ammonia a nitride is formed. H. Rose reported that ammonia unites with manganous chloride to form **manganous monamminochloride,** $MnCl_2.NH_3$; while W. Peters found that the salt at 160° forms **manganous hexamminochloride,** $MnCl_2.6NH_3$. In vacuo the hexammine loses 4 mols. of ammonia. F. Ephraim found the dissociation press., p mm., to be :

	50°	65°	70°	75·5°	80°	84°	87·5°	90·5°	91°
p	170	230	300	375	470	557	665	750	765

According to W. Biltz and G. F. Hüttig, anhydrous manganous chloride, at the temp. of solid carbon dioxide and alcohol, rapidly absorbs ammonia to form the white hexammine. At 76·3° the isothermal curve falls a little, and then remains horizontal until the composition approaches that of **manganous diamminochloride,** $MnCl_2.2NH_3$, the isothermal for which is 229·9°. There is then evidence of the formation of the monammine, Fig. 60. No other ammines exist under these conditions. W. Biltz and E. Birk studied the mol. vol. The dissociation press., p, and the heats of dissociation, Q Cals., are for manganous hexamminochloride, $MnCl_2.6NH_3$, at 59°, $p=218$ mm.; at 63°, $p=258$ mm.; at 76·5°, $p=495$ mm.; and the mean value of $Q=18\cdot8$ Cals. For the diammine, at 181°, $p=65$ mm., and $Q=18\cdot7$ Cals.; at 206°, $p=196$ mm., and $Q=18\cdot8$ Cals.; and at 230°, $p=407$ mm., and $Q=19\cdot1$ Cals. For the monammine, at 215°, $p=9\cdot4$ mm., and $Q=22\cdot1$ Cals.; at 230°, $p=28$ mm., and $Q=21\cdot75$ Cals.; and at 278°, $p=95$ mm., and $Q=22\cdot7$ Cals. F. Müller gave $-18°$ for the dissociation temp. of the hexamminochloride ; 87° for the pentamminochloride ; 240° for the diamminochloride ; and over 380° for the monamminochloride. F. Ephraim, and G. L. Clark also studied the hexammine ; and F. J. Garrick calculated values for the energy of co-ordination. W. Biltz and E. Rahlfs found that at still lower temp. and in contact with liquid ammonia it is possible to prepare **manganous dodecamminochloride,** $MnCl_2.12NH_3$, whose dissociation press., p mm., and heat of dissociation are at $-78\cdot5°$ (Fig. 61), $p=29\cdot5$ mm., and $Q=7\cdot14$ Cals.; and at $-65°$, $p=97\cdot5$ mm., and $Q=7\cdot15$ Cals.; this complex breaks down into **manganous decamminochloride,** $MnCl_2.10NH_3$, which at $-78\cdot5°$ has $p=20\cdot5$ mm., and $Q=7\cdot28$ Cals.; at $-65°$, $p=72$, and $Q=7\cdot27$; at $-60°$, $p=107$, and $Q=7\cdot28$; at $-55°$, $p=160$, and $Q=7\cdot28$; and at $-50°$, $p=220$, and $Q=7\cdot30$. F. Ephraim discussed the contraction in vol. attending the formation of the ammines. Neutral soln. of manganous salts with aq. ammonia give a partial precipitation of white manganous hydroxide, which is insoluble in excess of aq. ammonia and turns brown in air ; if the soln. be acidic, or if ammonium salts be present, precipitation does not occur. The precipitated hydroxide dissolves in soln. of ammonium salts with the liberation of ammonia; any admixed higher oxide remains undissolved. **Ammonium salt** soln. of manganous salts deposit brown hydrated oxide on exposure to air. W. Herz discussed the equilibrium phenomena between the ammonium and manganous salts. H. Rose observed that the precipitation by ammonia is hindered by tartaric acid. C. Vincent found that **dimethylaniline** behaves like ammonia ; and T. Curtius and F. Schrader, that **hydrazine hydrate** precipitates brown manganese hydroxide. H. Franzen and O. von Mayer obtained **manganous dihydrazinochloride,** $MnCl_2.2N_2H_4$; and A. Ferratini, **manganous trihydrazinochloride,** $MnCl_2.3N_2H_5Cl$, as a white crystalline powder which melts between 238° and 242° ; it is sparingly soluble in cold but easily soluble in warm alcohol with partial decomposition, and it is freely soluble in water. W. Feldt prepared **manganous dihydroxylaminochloride,** $MnCl_2.2NH_2OH$, as a stable, white powder which decomposes suddenly

at 150°–160°. N. Pfanner obtained **manganous hemitrihydroxylaminochloride,** $2MnCl_2.3NH_2OH.6H_2O$, by the action of manganese on an alcohol soln. of hydroxylamine hydrochloride. According to W. Prandtl, if a drop or two of a manganous salt soln. is added to a cold soln. of sodium nitrite in conc. hydrochloric acid, there develops a deep brownish-yellow coloration, due to the manganic chloride which is formed. Similarly, if oxalic acid is added to a soln. of sodium nitrite containing a mere trace of a manganous salt, the deep cherry-red colour of manganic oxalate appears. G. Hüfner observed that a soln. of manganous chloride absorbs **nitric oxide,** and inferred that the absorbed gas is partly united chemically with the solute, and part is dissolved in accord with Henry's law, so that the gas is more soluble in the salt soln. than it is in water alone. If v c.c. are absorbed, then a c.c. are loosely bound chemically, while b c.c. are absorbed in accord with Henry's law, $v = 2.5518 + 0.016538p$, where p mm. denotes the press. The coeff. of absorption is 0·06111. F. L. Usher, however, said that nitric oxide is indifferent towards manganous chloride in soln., and the solubility of the gas is similar to that of other inert gases, for it is less in the aq. soln. of manganous chloride than in water alone. It is difficult to prepare the gas of a high degree of purity. Manganous chloride dissolves in conc. **nitric acid,** forming a yellow soln. which soon becomes deep brown and opaque. According to A. Schlesinger, some manganic nitrate and chloride are formed, and when the soln. is boiled, a basic manganic nitrate is precipitated.
FIG. 60.—Dissociation Pressures of Manganous Hexamminochloride.
FIG. 61.—Dissociation Pressures of Manganous Dodecamminochloride.

F. W. O. de Coninck observed that when the hot soln. in sulphuric acid is mixed with nitric acid, chlorine is first given off, and then some nitrous fumes. In dil. soln. the manganous salts are not oxidized by nitric acid. L. P. de St. Gilles observed that an oxychloride is formed when manganous chloride is fused with **sodium nitrate** at 250° for a long time and the product washed with water. E. P. y Alvarez found that **pernitrates** form permanganate. H. Rose observed that heated manganous chloride is decomposed by **phosphine :** $3MnCl_2 + 2PH_3 = Mn_3P_2 + 6HCl$. H. Rose, and L. C. A. Barreswil found that when melted with syrupy **phosphoric acid** and potassium nitrate, an amethyst-blue glass is formed sensitive to 0·01 mgrm. of manganese ; for **sodium phosphate,** vide supra, the analytical reactions of manganese. H. P. Cady and R. Taft found that the chloride is insoluble in phosphoryl chloride. E. P. y Alvarez found that **perphosphates** form permanganate. R. Lang and co-workers observed that manganous salts are not in general oxidized by chromic acid or the chromates, but the oxidation is induced in the presence of **arsenites.** Thus, potassium dichromate in the presence of an arsenite oxidizes a manganese salt to a manganic salt : $Mn^{II} + Cr^{VI} + As^{III} = Mn^{III} + Cr^{III} + As^{V}$.

N. Schiloff and S. Pewsner studied the adsorption of the soln. by charcoal. J. Hoffmann prepared *manganous boroheptachloride,* $2MnCl_2.BCl_3$, by the action of chlorine on manganese boride at a red-heat. According to J. F. John, hydrated manganous chloride dissolves in **alcohol,** forming a green soln., which, according

to R. Brandes, burns with a reddish flame. R. Brandes gave for the percentage solubility, S, of manganous chloride in alcohol :

	75 per cent. alcohol				Absolute alcohol		
	10°	25°	43·75°	87·5° (b.p.)	11·25°	37·5°	76·25° (b.p.)
MnCl$_2$.	23·1	36·1	37·5	32·2	33·3	33·3	33·6 per cent.

and MnCl$_2$ crystallizes from these soln. on standing. The solubility, S, of the tetrahydrate in 75 per cent. alcohol at 10°, 25°, 43·75°, and 87·5° (b.p.) was found to be respectively S=53, 132, 144, 100·1 per cent. MnCl$_2$.4H$_2$O. G. C. Gibson and co-workers found the solubility of manganous chloride in methyl and ethyl alcohols, S grm. of salt per gram of alcohol, to be :

	CH$_3$OH					C$_2$H$_5$OH		
	15°	25°	35°	45°	55°	15°	35°	55°
S .	0·00190	0·00114	0·00064	0·00043	0·00029	0·00012	0·00014	0·00021

F. Bourion observed that the soln. in alcohol gives, on evaporation, rose-red crystals of the *trialcoholate*, MnCl$_2$.3C$_2$H$_5$OH, which has a sp. gr. of 1·5 at 10°, and a heat of formation of 2·36 Cals. The alcohol is all given off between 150° and 200°. R. Brandes said that manganous chloride is insoluble in **ether.** J. W. Döbereiner observed that the tetrahydrate is insoluble in absolute ether, and this solvent does not abstract the water of crystallization. If 15 to 20 vols. of ether are added to a vol. of absolute alcohol sat. with MnCl$_2$, manganous chloride is completely precipitated. R. Müller measured the solubility of manganous chloride in **pyridine.** R. Müller and co-workers, and F. Reitzenstein prepared a complex with pyridine, namely, **manganous dipyridinochloride,** MnCl$_2$.2C$_5$H$_5$N, and determined the electrical conductivity of its soln.; and L. Pincussohn obtained the complexes MnCl$_2$.C$_6$H$_5$N.HCl and MnCl$_2$.2C$_6$H$_5$N.HCl. According to R. B. Moore and J. Miller, the pyridine complex is more stable than the ammine. H. Grossmann and B. Schück obtained an insoluble precipitate by adding **guanidine carbonate** to a soln. of a manganous salt. G. A. Barbieri and F. Calzolari, and G. Scagliarini and G. Tartarini obtained a complex with **hexamethylenetetramine,** namely, MnCl$_2$.2C$_6$H$_{12}$N$_4$.10H$_2$O ; and A. Rosenheim and V. J. Meyer, a complex with **thiourea,** namely, MnCl$_2$.4CS(NH$_2$)$_2$, and he measured the conductivity of its soln. G. Bruni and A. Manuelli found that soln. of manganous chloride in **acetamide** are strongly ionized—*vide supra.* N. Castoro examined soln. in **urethane**—*vide supra.* A. Trillat observed a blue coloration is produced with **tetramethyldiamidodiphenylmethane**—*vide supra*, analytical reactions. Both the anhydrous salt and the tetrahydrate were found by R. Brandes to be insoluble in **turpentine.** L. Crismer studied the reactions of the manganous salts with turpentine, pinene, oil of lemons, and oil of thyme. E. Raymond studied the action of manganese salts on the oxidation of **benzaldehyde.** A. Naumann found that manganous chloride is insoluble in **ethyl acetate,** sparingly soluble in **methyl acetate,** and slightly soluble in **benzonitrile.** E. Rousseau observed the polymerization of **formol** by manganous chloride in ultra-violet light. According to O. W. Gibbs, C. R. Fresenius, and A. Classen, **oxalic acid** precipitates from concentrated but not from dilute soln. of manganous chloride crystalline manganous oxalate, which is soluble in hydrochloric or sulphuric acid, but not in oxalic acid or alcohol. A. Villiers, and W. Sander observed that when a mixture of equal vols. of a sat. soln. of oxalic acid, 25 per cent. hydrochloric acid, and 25 per cent. nitric acid is heated, there is no evolution of gas, but if a small quantity of any manganese salt is added, there is an almost immediate reaction, with the evolution of carbon dioxide and nitrogen, and the decomposition proceeds even if heating is discontinued. If the nitric acid is in excess, the oxalic acid is completely oxidized. With more conc. soln. the oxalic acid is slightly decomposed even in absence of manganese, but the difference produced by the addition of manganese is very marked. Many other compounds of the fatty group, such as glucose and saccharose, behave in the same

way. Compounds of the benzene group, on the other hand, yield chlorine substitution products instead of oxidation products ; benzene and toluene, for example, yield chlorobenzene and chlorotoluene respectively, even at the ordinary temp. A. Classen found that **potassium oxalate** precipitates all the manganese as oxalate, soluble in an excess of the oxalate, and precipitated from that soln. by acetic acid. The oxidation of oxalic acid by potassium permanganate is accelerated by the presence of manganous salts, as shown by A. V. Harcourt, A. V. Harcourt and W. Esson, and W. P. Jorissen and L. T. Reicher ; and likewise with the oxidation of **tartaric acid,** as shown by J. Krutwig. E. Darmois studied the effect of manganese chloride on the rotatory power of tartaric acid. S. Hakomori observed the formation of complex salts with tartaric acid and manganese salts. According to J. Spohr, J. H. Long, L. Kahlenberg and co-workers, and C. Kullgren, the speed of inversion of **sugar** is accelerated by the presence of a manganous salt. W. E. Garner and D. N. Jackson observed that the hydrolysis of aq. soln. of glucose or sucrose, in the presence of manganous chloride, is not appreciably affected by a magnetic field of 7000 to 8000 units. B. Köhnlein found that manganous chloride and propyl iodide do not readily exchange their halogen atoms at 145° to 150° in 4 hrs. R. Kuhn and K. Meyer noted how manganese salts accelerate the autoxidation of benzaldehyde, and V. K. la Mer and J. W. Temple, the autoxidation of quinol. A. Trillat measured the behaviour of manganous salts in acting as *inorganic enzymes,* by measuring the volume of oxygen absorbed in a given time by a definite quantity of gallic acid, quinol, pyrogallol, or tannin, in the presence of a manganous salt (chloride, sulphate, or acetate) ; under these conditions the manganous salts only become active in the presence of an alkali hydroxide or a salt of an alkaline earth, the increase in the rate of oxidation being proportional to the quantity of alkali hydroxide present, whilst for the same quantity of alkali hydroxide an increase in the quantity of the manganous salt beyond a certain limit has a paralyzing effect. Certain substances, such as arsenic acid, mercuric chloride, hydrocyanic acid, and hydrogen sulphide, which act as poisons on organisms, have the effect of retarding the reaction—*vide supra,* the physiological action of manganese. According to E. Rousseau, salts of manganese exposed to solar or ultra-violet radiation fix the ultra-violet energy which produces photocatalytic effects in sterilizing or activating ferments. W. Thomson and F. Lewis studied the action on **indiarubber.** C. F. Rammelsberg observed that the reddish-white precipitate produced by **potassium cyanide** in soln. of manganous salts quickly turns brown in air ; and F. von Ittner found that the precipitate is soluble in soln. of alkali cyanides and is decomposed by acids ; and J. Haidlen and C. R. Fresenius noticed that if the soln. of manganous salt be poured into that of potassium cyanide, the liquid becomes pale brownish-red and a dirty reddish-yellow precipitate is then formed ; this dissolves to a brownish-red liquid. Acids do not precipitate manganous cyanide from the liquid ; but the liquid deposits hydrated manganic oxide on exposure to air. Observations were also made by J. H. Eaton and R. Fittig. F. J. Otto found that **potassium ferrocyanide** gives a white precipitate with manganous salts ; it is easily soluble in hydrochloric acid, but not in an excess of potassium ferrocyanide, ammonium chloride, and other salts. C. H. Pfaff added that the precipitation occurs with one part of salt in 6000 parts of water ; and L. Blum also said that manganese can be so detected in a soln. containing 0·00004 grm. Mn. The brownish-yellow precipitate with **potassium ferricyanide** is not soluble in hydrochloric acid, but is decomposed by the hot acid. Observations were made by E. Lenssen, A. H. Allen, S. T. Orlowsky, C. N. Draper, and S. M. Deane. E. H. Miller and J. A. Mathews observed that $0.5N$-$MnCl_2$ gives a white precipitate with a $0.5N$-soln. of **potassium cobaltic cyanide.** A. Günther-Schulze studied the basic exchange of manganous chloride and permutite. O. C. Magistad observed that the manganese of manganous chloride and sulphate replaces lime in **zeolites.**

J. G. Hibbs and E. F. Smith examined the action of **magnesium** on aq. or

alcoholic soln. of manganous chloride, and obtained a deposit of what may have been manganese or a hydrated oxide of that element; I. Iitaka also studied the reaction. A. Terreil observed that manganous chloride explodes when it is heated with **zinc.** The action of **metals** on soln. of the salt has been discussed in connection with the metallic precipitation of manganese. Soln. of manganous salts give a white precipitate with **alkali hydroxides ;** the precipitate is not soluble in an excess of the alkali-lye, but is easily soluble in a soln. of an ammonium salt; it turns brown on exposure to air. E. Donath found that the precipitation is hindered by glycerol; and J. Lefort and P. Thibault, by gum arabic. H. Pélabon and M. Delwaulle observed that with **mercuric oxide** manganese oxides—Mn_3O_4, Mn_2O_3, and MnO_2—are formed as well as basic mercuric chlorides, depending on the conditions. E. Tiede and R. Piwonka studied the manganese-alumina phosphors. H. Rose showed that **alkali carbonates** give a white precipitate of manganous carbonate, which becomes brown if heated in air; the precipitation is incomplete in the cold or in the presence of ammonium salts; but the presence of tartaric acid makes no difference. H. Tamm, and C. R. Fresenius found that **ammonium carbonate** precipitates manganous carbonate completely from neutral soln. of manganous salts, even in the presence of ammonium salts; **potassium hydrocarbonate** gives a precipitate with conc. soln. of manganous salts; dil. soln. are rendered turbid, maybe after standing some time, but not if free carbon dioxide is in soln. For the action of the **alkaline earth carbonates,** *vide supra,* the analytical reactions of manganese. F. Wöhler, H. Barberi, and H. Rose discussed the possible formation of a manganite (*q.v.*) by the action of an ammoniacal soln. of **silver nitrate ;** S. T. Orlowsky studied the oxidizing action of silver nitrate, **mercuric nitrate,** and **copper sulphate ;** O. Kühling, the oxidizing action of **silver peroxide** to form permanganates; and A. Mailhe, and C. Rube, the action of **mercuric oxide.** H. Pélabon and M. Delwaulle represented the action of mercuric oxide when shaken with a soln. of manganese chloride : $3MnCl_2+4HgO=Mn_3O_4+2HgCl_2+2HgCl$, and with a larger proportion of mercuric oxide, manganic oxide : $2MnCl_2+3HgO =Mn_2O_3+HgCl_2+2HgCl$, or manganese dioxide : $MnCl_2+2HgO=MnO_2+2HgCl$, may be formed. For the oxidizing action of bismuthates, and for the action of permanganates, *vide supra,* permanganates ; R. Lang and J. Zwerina discussed the action of **chromic acid** on manganese salts. A. D. Brokaw found that when soln. of **gold chloride,** of varying conc., are mixed with soln. of manganous chloride, of conc. varying from $0.5N$- to saturation, no reaction can be detected, even after prolonged boiling. When, however, a very small amount of alkali is added to the cold mixture, manganese dioxide and gold are at once precipitated. The same result is obtained when a crystal of calcium carbonate is added to the mixture ; there is a slight effervescence, and after a few hours the crystal is covered with manganese dioxide containing flakes of gold. M. Holzmann found that hydrated manganese dioxide is precipitated by **ceric nitrate ;** and F. W. O. de Coninck, the action of **platinic chloride** in sunlight : $PtCl_4+2MnCl_2 \rightleftharpoons 2MnCl_3+PtCl_2$. O. T. Christensen found that **Fehling's soln.** is reduced by manganous salt soln. ; and G. Kassner observed that the presence of manganous salts favours the oxidation of **ferrous salt** soln. by atm. air ; S. T. Orlowsky found manganous salts in alkaline soln. are oxidized to manganic salts by **potassium dichromate.** The reaction was studied by R. Lang.

R. H. Brett found that the soln. of manganous hydroxide in one of ammonium chloride does not give a precipitate with hydrogen sulphide. H. Lessheim and co-workers discussed the constitution of the complex salts. According to O. Hautz, pale red monoclinic crystals of **ammonium manganous trichloride,** $NH_4Cl.MnCl_2.2H_2O$, are deposited when a mixed soln. of theoretical proportions of the component salts is evaporated. He said that the salt loses three-fourths of its water of crystallization at 100°, and that 100 parts of water dissolve 66·7 parts of the salt. A. Chassevant thought that he had prepared a similar salt. C. E. Saunders considered that there must have been a mistake in O. Hautz's

analysis, because he always obtained pale pink crystals of **ammonium manganous tetrachloride,** $(NH_4)_2MnCl_4.2H_2O$, or $2NH_4Cl.MnCl_2.2H_2O$, under the conditions employed by O. Hautz. This salt was also prepared by C. E. Rice, H. W. Foote and B. Saxton, and C. von Hauer. C. E. Saunders found that the *dihydrate* usually forms radiating groups of pale pink, almost colourless crystals, which are monoclinic and have the axial ratios $a:b:c=1.4913:1:1.4956$, and $\beta=95°\ 25'$. Two of the crystal axes are almost equal in length, and this with the habit gives the crystals the appearance of a rhombic dodecahedron. The cleavage is imperfect. The salt cannot be obtained pure by recrystallization from water, since it requires an excess of manganous chloride before it deposits crystals of a high degree of purity. The salt is not deliquescent in air, nor does it give up its water of crystallization in vacuo. C. von Hauer added that the crystals lose $1\frac{1}{2}$ mols. of water at 100° and the remainder at 135°, but C. E. Saunders added that the salt has a tendency to decompose as the water is given off at 110°. At a red-heat the salt loses ammonium chloride, etc., to form the tritatetrachloride. C. Hatchett found that aq. ammonia gives no precipitate with an aq. soln. of the salt. According to C. F. Rammelsberg, and A. Chassevant, the salt is a *monohydrate*, $(NH_4)_2MnCl_4.H_2O$, crystallizing in the cubic system ; S. U. Pickering also obtained a salt crystallizing in hard brown cubes which are said to be crystals of the mono-
FIG. 62.—Ternary System : MnCl$_2$-NH$_4$Cl-H$_2$O at 60°.
FIG. 63.—Ternary System : MnCl$_2$-NH$_4$Cl-H$_2$O at 25°.

hydrate. On the other hand, C. E. Saunders showed that the analyses were probably made on impure salts, for he obtained no evidence of the existence of the monohydrate. E. M. Farrer and S. U. Pickering reported that **ammonium manganous hexachloride,** $4NH_4Cl.MnCl_2.3H_2O$, was formed " by crystallizing soln. of the two chlorides." The specimen analyzed probably contained ammonium chloride as impurity, for C. E. Saunders obtained no evidence of its existence. E. M. Farrer and S. U. Pickering said that this salt, on being heated in dry air, gave off water and ammonium chloride at 100° ; but even at 220°, after prolonged heating, it still retained a considerable amount of water, although the ammonium chloride had all been expelled and about 4 per cent. of the salt had been oxidized. P. de Clérmont and H. Guyot boiled manganous sulphide with an excess of ammonium chloride, and found that the filtrate deposited ammonium manganous octodecachloride, $16NH_4Cl.MnCl_2.H_2O$, but there is nothing to show that the product was a chemical individual. N. Pfanner obtained **ammonium manganous heptachloride,** $3NH_4Cl.2MnCl_2.4H_2O$, by the action of manganese on a warm aq. soln. of hydroxylamine hydrochloride ; and **ammonium manganous tetramminotridecachloride,** $9NH_4Cl.2MnCl_2.4NH_3.H_2O$. O. Lehmann recognized the formation of isomorphous mixtures in the system MnCl$_2$-NH$_4$Cl-H$_2$O, and A. Johnsen studied their crystallography ; and H. W. Foote and B. Saxton showed that the 2 : 1 : 2-salt and ammonium chloride form two series of isomorphous mixtures

with a gap between the limiting compositions of each series. F. W. J. Clendinnen and A. C. D. Rivett studied the ternary system at different temp. The results for 60° and 25° are summarized in Figs. 62 and 63. There are three well-defined zones of isomorphous mixtures represented by the shaded areas, namely, AF, GH, and KD, with the gaps FG and HK. The curves ab, bc, and cd correspond with the solubility curves of the respective series, and the intersections b and c correspond with the gaps in the series. The alleged 2 : 1 : 2-compound falls well within the second series of isomorphous mixtures GH. The AD is a section across the temp.-conc. diagram of the binary system $NH_4Cl–MnCl_2.2H_2O$ at 60°. It is doubtful if ammonium chloride forms chemical compounds with manganous chloride under these conditions and in the generally accepted sense of the words. The isotherms between 10° and 70° are shown in Fig. 64, where the percentage weights of ammonium chloride in the liquids are taken as ordinates, and the percentage weights of ammonium chloride in the dry solids, as abscissæ These curves show the relative distribution of ammonium chloride in the liquid and solid phases. The distribution isotherms divide the field into several regions. A and B are regions of the existence of homogeneous, single-phase, isomorphous mixtures; and C is a heterogeneous region where solids of mean composition separate at stable equilibrium into two phases capable of existing together and with a soln. At 70° there is a considerable gap, ab, between the compositions of co-existing solids. With a fall of temp. the gap narrows, or the mutual solubility of ammonium chloride and manganous chloride dihydrate increases, showing that the formation of the solid soln. is exothermic. The composition of the solids steadily approach one another, as represented by the curve acb connecting the successive values of the two series of solid phases. At a temp. probably a little below 25° the regions A and B merge into one another and the two curves ac and bc join together; c is clearly a (lower) critical soln. point, and below it complete miscibility is characteristic of ammonium chloride and the dihydrate within the portion of the binary system studied. Thus at 20° there is no break in the distribution curve rst, although there is a most distinct point of inflexion at

Fig. 64.—Distribution of Ammonium Chloride in Solutions of Manganous Chloride in the Solid and Liquid Phases.

s. At 10° the inflexion is less, although still very obvious. There are disturbances due to metastable phenomena at 0° and −10°. At 60° and 32·5° metastable curves have been followed well into the region C. As indicated above, W. Feldt prepared **hydroxylamine manganous dichloride**, $2NH_2OH.MnCl_2$, but W. Meyeringh could not obtain a double salt by using a mixed soln. of hydroxylamine chloride and manganous chloride. N. Pfanner reported a number of **ammonium manganous hydroxylaminochlorides**—$NH_4Cl.MnCl_2.NH_2OH.H_2O$, by the action of manganese on a cold aq. soln. of hydroxylamine hydrochloride; $7NH_4Cl.MnCl_2.$ $2NH_2OH.7\frac{1}{2}H_2O$, from the brown product obtained in the preparation of $3NH_4Cl.2MnCl_2.4H_2O$; $3NH_4Cl.2MnCl_2.2NH_2OH.H_2O$, by boiling soln. of $9NH_4Cl.2MnCl_2.4NH_3.H_2O$, in alcohol; G. Spacu and L. Canton prepared **ammonium manganous hexamminotetrachloride**, $[Mn(NH_3)_6]Cl_2.2NH_4Cl$, by the action of dry ammonia on the powdered $(NH_4)_2MnCl_4.2H_2O$. As indicated above, W. Ferratini prepared **hydrazine manganous pentachloride**, $3N_2H_5Cl.MnCl_2$.

C. E. Saunders could not prepare a compound of lithium and manganous chlorides, but when an aq. soln. of the mixed salts is concentrated, the liquid becomes green. A. Chassevant, however, found that if a cold, conc. soln. con-

taining equivalents of lithium and manganous chlorides be allowed to crystallize, manganous chloride alone separates out; but if the soln. be concentrated on a water-bath until the rose-red liquid becomes yellowish, and then evaporated in vacuo, deliquescent crystals of **lithium manganous trichloride**, $LiCl.MnCl_2.3H_2O$, are formed. The crystals are said to be isomorphous with lithium cobaltous trichloride, $LiCoCl_3.3H_2O$. They break down into the individual chlorides when exposed to air. If the water is drawn from the crystals in vacuo, they are decomposed and the mass becomes brown. The crystals at 120° also lose water and hydrogen chloride; but the crystals can be dehydrated without decomposition in an atm. of hydrogen chloride; and the aq. soln. is stable in the presence of an excess of lithium chloride. The observations of C. Sandonnini and G. Scarpa on the f.p. of mixtures of lithium and manganous chlorides are summarized in Fig. 65. No compounds are formed. C. E. Saunders obtained some evidence of a **sodium manganous chloride**, but it was not possible to obtain the salt pure enough for analysis by cooling a hot, conc. soln. of the component salts. The impure product contained a large excess of manganous chloride. The observations of C. Sandonnini and G. Scarpa on the f.p. of mixtures of sodium and manganous chlorides are summarized in Fig. 66. There is evidence of the formation of $NaCl.MnCl_2$ and of $4NaCl.MnCl_2$. I. I. Krasikoff and I. T. Ivanoff found that 100 c.c. of a sat. soln. of sodium chloride dissolved 0·4 grm. of manganous chloride; and likewise with a
FIG. 65.—The Binary System: $MnCl_2$–LiCl.   FIG. 66.—The Binary System: $MnCl_2$–NaCl.   FIG. 67.—The Binary System: $MnCl_2$–KCl.

sat. soln. of potassium chloride at 18°. C. Sandonnini and G. Scarpa found that with a mixture of potassium and manganous chlorides (Fig. 67) there is formed **potassium manganous trichloride**, $KMnCl_3$, and also $4KCl.MnCl_2$. G. Spacu and L. Canton prepared white crystals of **potassium manganous hexamminotrichloride**, $[Mn(NH_3)_6]Cl_2.KCl$, from $KMnCl_3.2H_2O$ and dry ammonia. They also prepared the pyridine salt, $[Mn(C_5H_5N)_4]Cl_2.KCl$. According to C. E. Saunders, on adding potassium chloride to a hot, aq. soln. of manganous chloride, sufficiently concentrated to deposit crystals on cooling, much alkali chloride is dissolved, and pale pink radiating groups of crystals of a complex salt separate out as the liquid cools. Large crystals can be obtained by the spontaneous evaporation of the soln. The analysis of the salt corresponds with *dihydrated* potassium manganous trichloride, $KCl.MnCl_2.2H_2O$. The deliquescent crystals are triclinic pinacoids which have the axial ratios $a : b : c = 0·4001 : 1 : 0·3767$, and $\alpha = 82° 59'$, $\beta = 112° 41'$, and $\gamma = 90° 53'$. Twinning occurs about the (010)-plane, and the (010)-cleavage is well defined. O. Mügge also examined the crystals which he prepared in an analogous manner. The salt is freely soluble in water, but decomposes into its component salts when the attempt is made to recrystallize it from aq. soln. It is also decomposed by hydrochloric acid, with the deposition of potassium chloride. J. Süss examined the ternary system KCl–$MnCl_2$–H_2O at different temp., and he obtained for the percentage solubilities:

	MnCl₂	KCl	Solid phases
6°	40·23	—	MnCl₂.4H₂O
	35·94	9·41	MnCl₂.4H₂O ; KCl ; and KMnCl₃.2H₂O
	—	23·06	KCl
28·4°	44·46	—	MnCl₂.4H₂O
	43·28	8·66	MnCl₂.4H₂O ; and KMnCl₃.2H₂O
	38·65	13·79	MnCl₂.4H₂O ; KCl ; and K₂MnCl₄.2H₂O
	—	26·91	KCl
52·8°	50·14	6·01	MnCl₂.4H₂O ; MnCl₂.2H₂O ; and KMnCl₃.2H₂O
62·0°	51·86	—	MnCl₂.2H₂O
	49·95	6·67	MnCl₂.2H₂O ; and KMnCl₃.2H₂O
	44·05	12·49	KMnCl₃.2H₂O ; and K₂MnCl₄.2H₂O
	36·85	18·77	KMnCl₃.2H₂O ; and 4KCl.MnCl₂
	—	31·57	KCl

The whole of the results are plotted in Fig. 69 ; and the isothermal curve is plotted in Fig. 68. The region of stability of C. E. Saunders' complex salt, KMnCl₃.2H₂O, is indicated in Figs. 68 and 69. There is a transition temp. at 6° : MnCl₂.4H₂O, +KCl+Soln.=KMnCl₃.2H₂O+Soln. Below 6° the system contains MnCl₂.4H₂O, and above 6° it contains KMnCl₃.2H₂O ; at 28·4°, **potassium manganous tetrachloride**, K₂MnCl₄.2H₂O, is formed in minute, deliquescent, tetragonal pyramids
FIG. 68.—The Ternary System : KCl–MnCl₂–H₂O.
FIG. 69.—The Ternary System : KCl–MnCl₂–H₂O above 63°.

with the axial ratio $a:c=1:0·816$, sp. gr. 2·221, mol. vol. 140·1, and topic axial parameters $\chi=\psi=5·560$ and $\omega=4·531$. There is another transition at 62·6°, when **potassium manganous hexachloride**, 4KCl.MnCl₂, is formed (Figs. 68 and 69). The salt appears on C. Sandonnini and G. Scarpa's f.p. diagram, Fig. 67 ; and there is probably also a **sodium manganous hexachloride**, 4NaCl.MnCl₂, as indicated in Fig. 66. The potassium salt was reported by H. J. Johnston-Lavis to be a fumarole, or volcanic sublimation product, and was found in some fragmentary material ejected from Vesuvius in April, 1906. It was called **chloromanganokalite**. It appears in pale wine-yellow obtuse rhombohedra, which H. J. Johnston-Lavis and L. J. Spencer represented as hexagonal rhombohedra with the axial ratio $a:c=1:0·5801$. The deliquescent crystals are optically positive, and have a very low birefringence, and a mean refractive index of 1·59. The sp. gr. is 2·31, and the hardness 2·5. A. Lacroix thought that the crystals are pseudo-rhombohedral, and belong to the monoclinic system. J. Süss found the artificial crystals are hexagonal, with the axial ratio $a:c=1:0·594$, the topic axial parameters $\chi=7·808$ and $\omega=4·638$, sp. gr. 2·310, and mol. vol. 183·7.

According to R. Godeffroy, a pale rose-red crystalline powder is formed when a mixed soln. of manganous and rubidium chlorides is treated with conc. hydrochloric acid. The powder was regarded as anhydrous **rubidium manganous tetrachloride**, Rb₂MnCl₄, and when recrystallized from water it was said to form the

trihydrate. C. E. Saunders showed that the analyses were probably made with crystals having mechanically-included water; and that mixed soln. of the component salts in any proportions furnish crystals of the *dihydrate*, $Rb_2MnCl_4.2H_2O$. Even with a considerable excess of manganous chloride the trichloride, $RbMnCl_3$. $2H_2O$, was not obtained. The tetrachloride forms radiating groups of rose-red elongated, tabular, triclinic crystals. The crystals lose no water over calcium chloride, but all is lost at 110°. The salt is freely soluble in water, forming a neutral soln. R. Godeffroy said that a mixed soln. of cæsium and manganous chlorides deposits crystals of anhydrous **cæsium manganous tetrachloride**, Cs_2MnCl_4, when treated with conc. hydrochloric acid, and that the spontaneous evaporation of the aq. soln. gives the trihydrate, while the spontaneous evaporation of the hydrochloric acid soln. yields the hemipentahydrate. C. E. Saunders found that a mixed soln. of the component salts with an excess of cæsium chloride furnishes the *dihydrate*, $Cs_2MnCl_4.2H_2O$, in pale pink triclinic crystals which are not deliquescent in ordinary air and retain their water of crystallization when dried in a desiccator. The water of crystallization is lost at 105°. C. E. Saunders considers that R. Godeffroy's two hydrates represent the incompletely-dried dihydrate. A mixed soln. of the component salts was found by C. E. Saunders to furnish pale rose-red crystals of **cæsium manganous trichloride**, $CsMnCl_3.2H_2O$. The tabular, rhombic, bipyramidal crystals have the axial ratios $a:b:c=0.7919:1:1.2482$, and the cleavage is parallel to the (100)-face. The salt is freely soluble in water, and it can be crystallized from its aq. soln. It loses all its water of crystallization at 105°. The salt is not deliquescent under ordinary conditions, but when powdered it loses water over calcium chloride. E. H. Ducloux discussed the crystals as a means of detecting the salt microscopically.

C. E. Saunders could not prepare **cuprous manganous chloride**; nor could he obtain **cupric manganous chloride**, but G. André reported **copper manganous trioxydichloride**, as a *trihydrate*, $3CuO.MnCl_2.3H_2O$, to be formed by boiling for many hours freshly-precipitated cupric hydroxide with a soln. of manganous chloride (1:1). The product is washed with cold water, and dried at 100°. A. Werner represented the apple-green product by the formula $Cu_2(OH)_4.Cu(OH).MnCl_2$ with or without a mol. of water. A. Mailhe obtained the *tetrahydrate* by the action of a boiling soln. of manganous chloride on the brown hydrated oxide $4CuO.H_2O$. The green hexagonal plates are not decomposed by water—*vide supra* for $MnOCl_2$. P. A. von Bonsdorff obtained yellow rhombic prisms of **auric manganous octochloride**, $Au_2MnCl_8.8H_2O$, which are isomorphous with the magnesium salt. The octohydrate is stable in air in winter, but deliquescent in air in summer. H. Töpsöe and C. Christiansen obtained triclinic prisms of the *dodecahydrate* isomorphous with the cobalt salt.

C. E. Saunders was unable to prepare compounds of manganous chloride with the alkaline earths. A conc. soln. of mixed manganous and alkaline earth chlorides is green, as in the case of lithium chloride, but on concentration it furnishes only an impure amorphous powder. According to C. Sandonnini, no **calcium manganous chloride** is produced by fusing the component chlorides; instead, a complete series of solid soln. is formed with a minimum at about 583° and 62 mol. per cent. of $MnCl_2$— Fig. 70. A. Ferrari and A. Inganni found that mixed crystals are formed in all proportions, and they decomposed into their components at 475°. They gave 590° for the eutectic. Similarly with **strontium manganous chloride**, which shows on the thermal diagram, Fig. 71, a minimum at 499° and 45 mol. per cent. $MnCl_2$; but with barium and manganous chlorides there are two breaks on the f.p. curves, Fig. 72— one at 540° and 52 mol. per cent. $MnCl_2$, and another at about 923°. There is a eutectic at 503° and 64 mol. per cent. $MnCl_2$. Hence it is probable that there is a **barium manganous chloride** formed which decomposes when fused. According to C. Sandonnini's f.p. curve for mixtures of manganous and magnesium chlorides, Fig. 73, there is no sign of the formation of **magnesium manganous chloride**. C. E. Saunders found that a mixed soln. of the component chlorides in 70 per cent.

alcohol, on evaporation, gives flattened, feathery crystals of **magnesium manganous hexachloride,** $MgCl_2.2MnCl_2.12H_2O$. The salt is deliquescent in air, and loses some of its water of crystallization over calcium chloride. All the water of crystallization cannot be expelled by heat without decomposition. The crystals were not defined well enough for measurement. B. Gossner obtained the hexachloride $2MgCl_2.MnCl_2.12H_2O$ from a soln. of the two component salts containing an excess
FIG. 70.—Freezing-Point Curve of the System: $CaCl_2$-$MnCl_2$.

FIG. 71.—Freezing-Point Curve of the System: $SrCl_2$-$MnCl_2$.

FIG. 72.—Freezing-Point Curve of the System: $BaCl_2$-$MnCl_2$.

of magnesium chloride. The pale red hexagonal prisms or plates have the axial ratio $a : c = 1 : 1\cdot1649$. There is a cleavage on the (0001)-face. The birefringence is feeble and positive. The sp. gr. is $1\cdot802$. C. Sandonnini obtained no evidence of the formation of **zinc manganous chloride** on the f.p. curve, Fig. 74. The curve descends from that of manganous chloride to that of zinc chloride; and the temp. of the eutectic coincides with the f.p. of zinc chloride. The eutectic temp. decreases
FIG. 73.—Freezing-Point Curve of the System: $MgCl_2$-$MnCl_2$.

FIG. 74.—Freezing-Point Curve of the System: $ZnCl_2$-$MnCl_2$.

FIG. 75.—Freezing-Point Curve of the System: $CdCl_2$-$MnCl_2$.

slightly with increasing amounts of manganous chloride. C. Sandonnini and G. Scarpa found that the f.p. curve of mixtures of cadmium and manganous chlorides, Fig. 75, shows a complete series of solid soln. between the f.p. of the two components. C. von Hauer evaporated spontaneously a conc. soln. of a mol of manganous chloride and 2 mols of cadmium chloride, and obtained rose-red crystals, which after many recrystallizations became almost colourless **cadmium manganous hexachloride,** $2CdCl_2.MnCl_2.12H_2O$. The crystals deliquesce in moist air, and effloresce

in dry air; they form a turbid soln. with hot water; they lose about 10 mols. of water at 100°, and 2 more at 160°. The crystals melt at a dull red-heat. If a mixture of 2 mols. of manganous chloride and one mol. of cadmium chloride is evaporated, manganous chloride forms the first crop of crystals, and this is followed by the crystallization of the preceding complex salt. P. A. von Bonsdorff evaporated over conc. sulphuric acid a soln. of manganous chloride sat. with mercuric chloride,
FIG. 76.—Freezing-Point Curve of the System : SnCl₂–MnCl₂.
FIG. 77.—Freezing-Point Curve of the System : PbCl₂–MnCl₂.

and obtained a crop of crystals of mercuric chloride followed by pale red rhombic columns of **mercuric manganous tetrachloride**, $HgCl_2.MnCl_2$. The crystals effloresce over conc. sulphuric acid, and deliquesce in moist air, but they are stable in moderately dry air. R. Varet said that the heat of formation from soln. of the component salts at 18° is 0·96 Cal.; and for **mercuric manganous hexachloride**, $2HgCl_2.MnCl_2$, 1·12 Cals.

J. Kendall and co-workers observed the possible formation of **aluminium manganous chloride**, $2AlCl_3.MnCl_2$. J. Gewecke evaporated an aq. soln. of a mol of manganous chloride and 2 mols of thallic chloride, and obtained **thallic manganous octochloride**, $2TlCl_3.MnCl_2.6H_2O$, in pale rose-coloured needles, which can be purified by recrystallization. The salt is not formed in acidic soln. S. M. Jörgensen prepared **stannic manganous chloride**, or **manganous chlorostannate**, $MnSnCl_6.6H_2O$, by evaporating a mixed soln. of the component salts. The pale red trigonal rhombohedra have the axial ratio $a:c=1:0.5194$, and $a=112° 6'$. The (101)-cleavage is marked; and the optical character is positive. The sp. gr. is 2·215. The crystals deliquesce in moist air, and effloresce in dry air; they lose water and stannic chloride at 100°. C. Sandonnini and G. Scarpa observed no evidence of the formation of **stannous manganous chloride** on the f.p. curve, Fig. 76; there is a eutectic at 233° and 95 mol. per cent. SnCl₂; and a similar result was obtained with respect to **lead manganous chloride**, Fig. 77, where the system has a eutectic at 408° and 70 mol. per cent. PbCl₂.

§ 18. The Higher Manganese Chlorides

According to G. Forchhammer,[1] when manganese dioxide is treated with cold, conc. hydrochloric acid, a dark brown soln. is formed. The same dark liquid was mentioned by C. W. Scheele. The liquid evolves chlorine slowly at ordinary temp., but more quickly when heated, until finally the liquid appears colourless and it contains only manganous chloride in soln. If the brown soln. is largely diluted with water, it remains clear, but soon becomes turbid and deposits a copious brown precipitate of hydrated manganese dioxide admixed with other oxides. If manganese hemitrioxide be similarly treated, a similar brown soln. is formed. G. Forchhammer concluded that the brown liquid contains manganese trichloride. W. W. Fischer inferred from experiments on this subject that when the manganese oxides higher than the monoxide are treated with an excess of conc. hydrochloric acid, brown liquids are formed which contain a highly chlorinated compound of manganese, and that this product is easily resolved into manganous chloride and chlorine. When the brown liquid is diluted with water, hydrated manganese dioxide is precipitated. The soln. all have identical properties, and probably contain the same compound. W. W. Fischer inferred that the compound is **manganese tetrachloride**, $MnCl_4$; and S. U. Pickering, **manganese trichloride**, $MnCl_3$, or Mn_2Cl_6. W. W. Fischer represented the formation of the tetrachloride : $MnO_2 + 4HCl = 2H_2O + MnCl_4$, and S. U. Pickering : $2MnO_2 + 8HCl = Mn_2Cl_6$

$+Cl_2+4H_2O$. W. W. Fischer based his conclusion mainly on his observations (i) that water always precipitates a definite substance from the brown liquor containing the higher chloride; (ii) that the precipitate is always manganese dioxide; and (iii) that the atomic ratio of the precipitated manganese to the loosely combined chlorine of the higher chloride in the soln. is as 1 : 2. On the other hand, S. U. Pickering showed (i) that water does not precipitate a definite substance; (ii) that the precipitate is a mixture of the dioxide and hemitrioxide in variable proportions; and (iii) that the atomic ratio of the precipitated manganese to the available chlorine of the higher chloride in the soln. is not 1 : 2. W. W. Fischer represented the reaction with water: $MnCl_4+2H_2O$ $=MnO_2+4HCl$, and with potassium iodide : $MnCl_4+2KI=MnCl_2+2KCl+I_2$, but S. U. Pickering showed that the same result would be obtained if the higher chloride is any chloride corresponding with Mn_nCl_{2n+2}; for example, with water : Mn_2Cl_6 $+2H_2O=MnO_2+MnCl_2+4HCl$, and with potassium iodide : Mn_2Cl_6+2KI $=2MnCl_2+2KCl+I_2$. S. U. Pickering was never able to get more than half the manganese as a precipitate, and he inferred that if the equation $Mn_2Cl_6+2H_2O$ $=MnO_2+MnCl_2+4HCl$ be correct, the amount of precipitated manganese should increase if manganous chloride be added to the soln., but if the tetrachloride be treated, the amount should remain stationary. The addition of manganous chloride does increase the amount of manganese dioxide precipitated, in agreement with the trichloride hypothesis. Again, if the substance be tetrachloride, 100 per cent. of manganese should be precipitated at a low temp., and only 50 per cent. if the substance be trichloride. Actually, at 60°, only 10 per cent. was precipitated, and at a low temp., 50 per cent. H. M. Vernon favoured W. W. Fischer's hypothesis, because if the action of hydrochloric acid be in accord with $2MnO_2$ $+8HCl=Mn_2Cl_6+Cl_2+4H_2O$, half the available chlorine ought to be evolved very rapidly, especially at low temp. This is not the case, and he hence concluded that the tetrachloride is the first product of the reaction. The brown soln. of manganese dioxide in hydrochloric acid is supposed to contain much free chlorine in soln. which is given off only gradually. H. M. Vernon showed that in a current of air the soln. at −26° lost only a small quantity of chlorine, and no solid chlorine hydrate was formed. At a higher temp. the quantity of chlorine evolved increases proportionally with the temp.; but at ordinary temp. the chlorine given off is only half that which would be expected if the trichloride were formed. L. Wacker also favoured the tetrachloride hypothesis, because when chlorine gas is passed into a soln. of manganous chloride in conc. hydrochloric acid, a brown soln. is obtained resembling that produced when manganese dioxide is dissolved in conc. hydrochloric acid; and manganese dioxide or one of its hydrates is formed when either soln. is diluted with water. L. L. de Koninck observed that when one or two drops of nitric acid of sp. gr. 1·35 to 1·40 are added to a boiling soln. of a manganese salt in fuming hydrochloric acid, the colour of the liquid changes to a very dark green with a tinge of yellow, owing to the formation of manganese tetrachloride or possibly of a chloromanganic acid, H_2MnCl_6. This compound is very stable in hydrochloric acid; the coloration is destroyed only by prolonged boiling. A. N. Campbell prepared the brown liquid in the anode compartment during the electrolysis of soln. of manganous chloride, and he showed by means of the ultramicroscope that it does not contain colloidal particles of manganese dioxide, but is rather a soln. of manganous chloride containing 0·0185 to 0·0188 mols of $MnCl_4$ per litre. The mode of preparing the liquid was as follows :

The electrolysis cell consisted of a rectangular glass jar containing a porous pot. The porous pot contained the anolyte of $3M$-manganous chloride, to which an eq. vol. of conc. hydrochloric acid had been added, and the main body of the cell the catholyte of ammonium chloride, containing 250 grms. of the salt per litre. Both anode and cathode were sheets of platinum foil. An anodic current density of 6 amp. per sq. dcm. was used, corresponding to a total current of 6 ampères. Current was passed for two and a half hrs., during which time the temp. rose from 18° to 47°. Rise of temp. was not prejudicial to the process. On the other hand, neither current density nor manganese concentration can be much reduced.

C. E. Rice showed that the dissociation of the chlorinated compound is reversible, for if a cooled soln. of manganous chloride be sat. with chlorine and left to stand for some days, or if a hydrochloric acid soln. of manganous chloride be left in a sealed tube with chlorine hydrate at ordinary temp., the liquid gradually darkens in colour, and this effect reaches a maximum in a few days. The result corresponds with the balanced reaction : $2MnCl_3 \rightleftharpoons 2MnCl_2 + Cl_2$. In support of the trichloride hypothesis, the brown liquid sat. with hydrogen chloride, cooled by a freezing mixture, and treated with ammonium chloride furnishes complex salts of the trichloride of the type : $2RCl.MnCl_3.nH_2O$. G. Neumann obtained similar results ; and R. J. Meyer and H. Best also favoured the trichloride hypothesis, because they obtained complex salts with pyridine and quinoline hydrochlorides from soln. of manganese dioxide in alcohol or ether sat. with hydrogen chloride. F. Olsson obtained complex salts $MnCl_3.2RCl$, when R is an organic base ; and likewise salts $MnCl_4.2RCl$. R. H. Weber found that the magnetic susceptibility of the brown soln. is of the same order as results obtained with soln. of other salts of tervalent manganese.

J. Nicklès showed that when hydrogen chloride acts on manganese dioxide suspended in dry ether, a green soln. is obtained which *variaient singulièrement* in composition, but contains manganese and chlorine in the proportion Mn : Cl $= 1 : 2.58$. In one case the product agreed with $MnCl_4.12(C_2H_5)_2O.2H_2O$, but, as shown by S. U. Pickering, the same analytical data would agree with $MnCl_3.12(C_2H_5)_2O.HCl.2H_2O$. J. Nicklès also obtained a product $MnCl_3.2C_5H_{11}OH.HCl.8H_2O$, by similarly treating manganese hemitrioxide in the presence of amyl alcohol. According to O. T. Christensen, when chlorine is passed into absolute ether containing pure manganese peroxide in suspension and cooled by means of water, the liquid acquires after some time a violet colour so intense that it appears almost black and opaque. If the treatment with chlorine is prolonged, and the cooling insufficient, a reduction takes place, and manganous chloride gradually separates. The mixture should be shaken frequently, and kept from much light. If the dark liquid is poured off, a substance is obtained partly soluble in ether with intense violet colour ; the insoluble residue is unchanged manganese oxide. The ether poured off gives after some hours an abundant separation of manganous chloride and loses its colour. When conc. hydrochloric acid, of sp. gr. 1.19, is shaken with absolute ether, two layers are obtained, the lower a soln. of ether in hydrochloric acid, and the upper a soln. of hydrochloric acid in ether. When these are treated separately with manganese peroxide, the ethereal hydrochloric acid soln. acquires a green, whilst the hydrochloric acid containing ether acquires a violet colour. Hence the colour appears to depend on the amount of water present. O. T. Christensen concluded that when hydrochloric acid acts on manganese dioxide, manganese trichloride is formed, but at 10° more chlorine is taken up, forming the tetrachloride. Manganese hemitrioxide yielded the same chloride, $MnCl_3$, as manganese dioxide when it was treated with a soln. of hydrogen chloride in ether. The atomic ratio Mn : Cl for active chlorine in excess of that required for manganous chloride is approximately 1 : 1, in agreement with the assumption that the soln. of manganese dioxide in ether sat. with hydrogen chloride contains manganese trichloride. Freshly prepared soln. of manganese hemitrioxide in ether sat. with hydrogen chloride contain very little free chlorine. According to R. J. Meyer and H. Best, manganese oxide—Mn_2O_3, Mn_3O_4, or MnO_2—dissolves in absolute alcohol or ether saturated with hydrogen chloride, forming a green soln. of manganese trichloride which is decomposed by water and by evaporation in vacuo over sulphuric acid, so that the trichloride could not be isolated. The green soln. forms the well-defined salts with the hydrochlorides of pyridine and quinoline indicated above.

According to M. Berthelot, an aq. soln. of manganous chloride absorbs less chlorine than does water, and with the evolution of 4400 cals. instead of 3000 cals. per mol of chlorine. If, however, hydrochloric acid be present, more chlorine is absorbed, with the evolution of a greater amount of heat—namely, 9200 cals. per

mol. of chlorine—and a brown soln. is formed which is supposed to contain the hydrochloride $MnCl_3.nHCl$ or $MnCl_4.nHCl$. B. Franke said that the green soln. of manganese dioxide in ether saturated with hydrogen chloride contains the acid H_2MnCl_6, which can be obtained in green, oily drops ; and that the manganous salt of this acid, $Mn(MnCl_6)$, i.e. Mn_2Cl_6, is present in the soln. R. J. Meyer and H. Best found no support for B. Franke's hypothesis. W. B. Holmes supposed that his work on the action of hydrogen chloride on manganese dioxide suspended in carbon tetrachloride supported the assumption that manganese tetrachloride is the first product of the reaction, although W. B. Holmes and E. V. Manuel did not consider the demonstration of the existence of the tetrachloride to be satisfactory.

According to A. Miolatti, the facts can be reconciled with the assumption that the brown soln. of manganese dioxide in conc. hydrochloric acid is a system in which there is a complex balance of reversible reactions. H. M. Vernon's observations show that both the trichloride and tetrachloride have a marked dissociation press., and that the former is less readily decomposed than the latter. Hence, the system contains $2MnCl_4 \rightleftharpoons 2MnCl_3 + Cl_2$ and $2MnCl_3 \rightleftharpoons 2MnCl_2 + Cl_2$. The hydrolytic changes $MnCl_4 + 4H_2O \rightleftharpoons Mn(OH)_4 + 4HCl$ and $MnCl_3 + 3H_2O \rightleftharpoons Mn(OH)_3 + 3HCl$ are driven back in the presence of an excess of conc. hydrochloric acid. At the same time, complex hydrochlorides are probably formed, e.g. $MnCl_4 + HCl \rightleftharpoons HMnCl_5$; $MnCl_4 + 2HCl \rightleftharpoons H_2MnCl_6$; as well as $MnCl_3 + HCl \rightleftharpoons HMnCl_4$; $MnCl_3 + 2HCl \rightleftharpoons H_2MnCl_5$. If any component of the complex system of balanced reactions is withdrawn by precipitation, etc., then, in accord with the mass law, the whole of the dependent equilibria are displaced until the balance is restored. The brown soln. may thus contain in soln. all three chlorides—$MnCl_2$, $MnCl_3$, and $MnCl_4$—as well as chlorine. This is supported by A. Chilesotti's observation that the electrolytic oxidation of manganous chloride does not proceed in steps $Mn^{..} \rightarrow Mn^{...} \rightarrow Mn^{....}$, but both the changes $Mn^{..} \rightarrow Mn^{...}$ and $Mn^{..} \rightarrow Mn^{....}$ may take place. R. F. Weinland and P. Dinkelacker showed that in the action of cold, conc. hydrochloric acid on permanganates salts corresponding with R_2MnCl_6 are first formed, and then the salts R_2MnCl_5. When organic solvents are used in place of water, the balanced equilibria are displaced in favour of manganese trichloride, or else the hydrochloride of manganese trichloride is more stable than is the case with the hydrochloride of the tetrachloride.

According to W. B. Holmes, when dry hydrogen chloride is bubbled through a mixture of 5 grms. of manganese dioxide and 200 c.c. of carbon tetrachloride in a flask constantly agitated, and cooled by a mixture of ice and salt, there is formed a greenish-black solid. No manganese passes into soln., but the liquid is coloured yellow by the dissolved chlorine. The solid can be washed with a large amount of carbon tetrachloride, then with carbon disulphide containing a little ether, and dried in a desiccator over potassium hydroxide, and sulphuric acid ; it slowly decomposes on standing and chlorine and hydrogen chloride are given off. The solid is supposed to be a mixture of manganese tri- and tetrachlorides mixed with some manganous chloride. To remove the manganese trichloride the residue was washed with ether cooled with solid carbon dioxide. Two-thirds of the contained manganese trichloride is thus removed ; it was then washed with 100 c.c. of cold ether, and the analysis of the violet ethereal soln. shows that it contained manganese trichloride. About half of the original residue consists of manganese trichloride. The solid could not be obtained pure enough for analysis by the evaporation of the ethereal soln. in a current of cold air, because decomposition always set in. Hence, the ethereal soln. was analyzed. Manganese trichloride is a nearly black solid with a slight green tinge, and it is immediately decomposed by water ; when the salt is heated, chlorine is evolved, and if left in a desiccator it changes into a mixture of manganous chloride and manganese tetrachloride : $Mn_2Cl_6 = MnCl_2 + MnCl_4$. It dissolves in alcohol, forming a wine-red soln. containing the tetrachloride, but if this soln. is diluted with ether and kept cold, it forms a violet soln. of the trichloride.

When the ethereal soln. of the trichloride is poured into water, only half the manganese is precipitated.

All the trichloride cannot be removed from the original residue by washing with ether, probably because of the slight decomposition of the tetrachloride. A soln. of the tetrachloride in alcohol was prepared for analysis because the solid was always contaminated with manganous chloride. Analyses agreed with the assumption that manganese tetrachloride was present in the soln. of the residue in cold absolute alcohol ; but W. B. Holmes and E. V. Manuel regard the proof of the existence of the tetrachloride to be very unsatisfactory. The solid supposed to be tetrachloride was said to be a reddish-brown solid, stable at ordinary temp. if kept dry, but it quickly decomposes on exposure to moist air. It can be kept several weeks in a desiccator without undergoing appreciable decomposition. But in a large amount of water the tetrachloride gives an immediate precipitate, probably hydrated manganese dioxide. Heated to 100° it gives off chlorine, and a residue of manganous chloride remains. When the tetrachloride is suspended in ether and kept cold, it slowly decomposes into the trichloride, imparting the characteristic violet colour to the solution. If an excess of alcohol is added to this solution, some tetrachloride is again formed. Suspended in ether with mercurous chloride it decomposes more rapidly, but all the ordinary reducing agents such as can be used in a solution nearly anhydrous cause immediate decomposition without the intermediate stage. Absolute alcohol seems to be the only solvent which will dissolve the tetrachloride without rapid decomposition. If the alcohol contains a little water the soln. is decolorized more quickly.

O. T. Christensen recommended the following process for preparing a soln. of manganese trichloride suitable for making complex salts. A mixture of 5 grms. of potassium permanganate and 50 c.c. of absolute alcohol, and an equal vol. of alcohol saturated with hydrogen chloride is shaken and cooled ; chlorine and acetaldehyde are given off and a dark green soln. is formed. When the soln. is cooled by a freezing mixture, it deposits the potassium chloride. When the green ethereal or alcoholic soln. of the trichloride is treated with a little water, manganic hydroxide, $Mn(OH)_3$, is precipitated. If a sufficient excess of hydrogen chloride is present, the soln. can be boiled a short time without decomposition, but with a prolonged boiling, or evaporation in vacuo over sulphuric acid and potassium hydroxide, the soln. is decolorized. The addition of an alcoholic soln. of mercuric chloride also reduces the green soln. If the green soln. is diluted with alcohol free from hydrogen chloride, it becomes reddish-violet or reddish-brown, but the green colour is restored by adding ether. A. N. Campbell found the normal potential of quadrivalent manganese ions—assumed to be present in the brown liquid he prepared electrolytically—in the presence of bivalent manganese ions is, on the hydrogen scale, 1·465 volt at 15°. R. H. Weber studied the magnetic susceptibility of soln. of hydrated manganese dioxide in hydrochloric acid.

A. F. Rogers obtained small emerald-green crystals of a mineral with the composition of a **manganic hexoxydichloride,** $Mn_4Cl_2O_6.3H_2O$, from San José, California ; he called it **kempite**—after J. F. Kemp. The rhombic crystals have the axial ratio : $a : b : c = 0·677 : 1 : 0·747$; the sp. gr. is 2·94, the hardness 3·5, and the indices of refraction $a = 1·684$, $\beta = 1·695$, and $\gamma = 1·698$. The mineral dissolves in hydrochloric acid with the evolution of chlorine.

Chlorohypomanganites.—H. Lessheim and co-workers discussed the constitution of the complex salts. According to G. Neumann, **ammonium manganic pentachloride,** $(NH_4)_2MnCl_5$, is obtained when manganese dioxide is allowed to remain for a considerable time in contact with conc. hydrochloric acid, kept cool by immersion in a freezing mixture of ice and salt, and sat. with hydrogen chloride and chlorine ; the brown soln. thus obtained, when filtered and treated with a cold soln. of ammonium chloride, yields the compound in violet-brown crystals. R. F. Weinland and P. Dinkelacker obtained the ammonium salt, $(NH_4)_2MnCl_5.H_2O$, as a reddish-black crystalline powder, by adding potassium permanganate and a conc.

soln. of ammonium chloride to a 40 per cent. aq. soln. of hydrochloric acid cooled by ice and salt; the potassium salt of the tetrachloride is precipitated, and when the mother-liquor is treated with more ammonium chloride, the salt $(NH_4)_2MnCl_5$ is precipitated. C. E. Rice obtained this salt when a mixture of 50 grms. of one of the higher manganese oxides and 250 c.c. of cold, conc. hydrochloric acid was sat. with dry hydrogen chloride while being cooled in a freezing mixture. After the mixture had stood for half an hour the clear liquor was decanted and treated with a few c.c. of a sat. acidified soln. of ammonium chloride, added drop by drop. The mixture, cooled by a freezing mixture, was again sat. with hydrogen chloride and allowed to stand half an hour. The crystals were filtered off, washed with cold, sat. hydrochloric acid, drained on a porous plate, and left for some days over soda-lime under reduced press. The analysis corresponded with $(NH_4)_2MnCl_5.H_2O$. The crystals are perfectly transparent under the microscope, transmitting a ruby-coloured light. They have a slightly pungent odour, and may be raised to a temp. of 100° without perceptible change; above that temp., however, they evolve chlorine and water, and if heated in a current of air, leave a white residue of manganous chloride and sublimed ammonium chloride. They dissolve in hydrochloric acid, yielding a liquid resembling that from which they were obtained. Water at once decomposes them, about half the total manganese separating as hydrated higher oxide and half remaining in soln. as manganous chloride. If the complex salts of manganese tetrachloride be called *chloromanganites*, as is commonly the case, then these salts can be designated by the awkward term *chlorohypomanganites*. According to R. J. Meyer and H. Best, the green soln. of a higher oxide of manganese in absolute alcohol or ether sat. with hydrogen chloride, when treated with pyridine hydrochloride furnishes needle-like crystals of **pyridine manganic pentachloride,** $2C_5H_5N(HCl).MnCl_3$; and with quinoline hydrochloride, acicular crystals of **quinoline manganic pentachloride,** $2C_9H_7N(HCl).MnCl_3$. F. Olsson obtained a number of complexes with the chlorides of the quaternary ammonium bases.

G. Neumann, C. E. Rice, and R. F. Weinland and P. Dinkelacker prepared **potassium manganic pentachloride,** $2KCl.MnCl_3$, by the methods they employed for the ammonium salt. O. Stelling and F. Olsson studied the X-ray spectrum. R. J. Meyer and H. Best also prepared it by reducing a soln. of potassium permanganate with acetic acid with the addition of potassium acetate, and sat. the liquid with hydrogen chloride. If the soln. be only partially sat. with hydrogen chloride, *potassium manganese dodecachloride,* $5KCl.MnCl_4.MnCl_3$, is formed. C. E. Rice regarded potassium manganic pentachloride as a monohydrate, and said that the potassium and ammonium salts are isomorphous with the corresponding complex salts of ferric chloride. The other observers said that the salt is anhydrous. R. F. Weinland and P. Dinkelacker prepared **rubidium manganic pentachloride,** $2RbCl.MnCl_3$, by the process which they employed for the ammonium salt; and similarly with R. J. Meyer and H. Best's, and R. F. Weinland and P. Dinkelacker's preparations of **cæsium manganic pentachloride,** $2CsCl.MnCl_3$. The corresponding **thallous manganic pentachloride,** $2TlCl.MnCl_3$, could not be prepared by R. J. Meyer and H. Best.

Chloromanganites.—G. Lunge and B. Zahorsky mentioned the existence of a possible **manganese oxychloride,** $MnOCl$, and G. Lunge, **manganese trioxydichloride,** $Cl-MnO_2-OCl$, in the brown liquid obtained by the action of hydrochloric acid on manganese dioxide. A. Gorgeu obtained what he regarded as **manganese hexoxydichloride,** $2Mn_2O_3.MnCl_2$, by heating manganous chloride in moist air until about half is decomposed and washing the product with water. L. P. de St. Gilles also reported **manganese enneaoxydichloride,** $3Mn_2O_3.MnCl_2$, but there is no evidence confirming the individuality of these products. R. F. Weinland and P. Dinkelacker treated calcium permanganate with 40 per cent. hydrochloric acid cooled by a mixture of ice and salt; an aq. soln. of ammonium chloride was added, and **ammonium chloromanganite,** $(NH_4)_2MnCl_6$, crystallized out. F. Reitzenstein prepared **pyridine chloromanganite,** $2C_5H_5N.MnCl_4$, by adding pyridine to a soln. of

manganese dioxide in conc. hydrochloric acid. J. G. F. Druce did not obtain **potassium manganese hexachloride**, $MnCl_4.2KCl$, or K_2MnCl_6, by passing chlorine into a soln. of potassium and manganese chlorides. R. J. Meyer and H. Best found that **potassium chloromanganite**, K_2MnCl_6, is formed as a black crystalline precipitate when an acetic acid soln. of potassium permanganate, without potassium acetate, is sat. with hydrogen chloride. R. F. Weinland and P. Dinkelacker also obtained it by a method analogous to that employed for the ammonium salt; and likewise also with **rubidium chloromanganite**, Rb_2MnCl_6. R. J. Meyer and H. Best could not obtain **thallous chloromanganite**. N. Bjerrum and G. H. Hansen could not prepare complexes with chromic chloride.

Oxychlorides.—According to J. B. A. Dumas, when a mixture of a soln. of potassium permanganate in conc. sulphuric acid is mixed with fused sodium chloride and heated to 30° or 40° in a retort, a reddish or greenish vapour is given off, and it condenses at $-15°$ to $-20°$, forming a greenish-brown liquid. The vapour in contact with moist air decomposes, forming hydrochloric and permanganic acids. H. Aschoff also obtained the greenish-brown liquid by the action, under similar conditions, of sodium chloride on a soln. of manganese heptoxide in sulphuric acid. The smell of the gas recalls that of chlorine oxide, and ozone. The gas attacks the respiratory organs. E. Luck, and W. Friederichs studied the absorption spectrum. When the drops of liquid are heated on a water-bath, detonation occurs at the same temp. as with manganese heptoxide. Water attacks the liquid vigorously, forming chlorine and manganese dioxide. J. B. A. Dumas thought that he was dealing with *manganese heptachloride*; H. Aschoff's analysis corresponds with **manganese trioxychloride**, MnO_3Cl, but it may be nothing more than a soln. of chlorine or a chloride in manganese heptoxide. The product thus recalls F. Wöhler's MnO_3F, and B. Franke's $(MnO_3)_2SO_4$.

§ 19. Manganese Bromides

Anhydrous **manganese dibromide,** or **manganous bromide,** $MnBr_2$, was prepared, as a pale rose-red mass, by C. J. Löwig,[1] by the action of bromine vapour on heated manganese ; and J. B. Berthemot, by heating the hydrated salt out of contact with air. A soln. of the salt was prepared by A. J. Balard by the action of bromine on manganous oxide ; by J. B. Berthemot, by digesting manganese with bromine-water ; and by C. J. Löwig, by dissolving manganous carbonate in hydrobromic acid. When the aq. soln. is evaporated, it furnishes a pale red powder (C. J. Löwig), or acicular crystals of the *tetrahydrate*, $MnBr_2.4H_2O$, which are coloured a deeper rose-red than the corresponding chloride (J. C. G. de Marignac). H. Lescoeur said that if the tetrahydrate is allowed to effloresce in air, it forms the *monohydrate*, $MnBr_2.H_2O$, as a rose-red powder ; P. Kutznetzoff also obtained it by heating the tetrahydrate at its m.p., 64·3°. If the aq. soln. be cooled to —14°, or even to 0°, P. Kutznetzoff said that crystals of the *hexahydrate*, $MnBr_2.6H_2O$, are deposited. P. Kutznetzoff gave 13° for the transition temp. for the hexahydrate and tetrahydrate ; and 64° for the transition temp. for the tetrahydrate and the monohydrate. The solubility data of A. Étard, when S denotes the number of grams of $MnBr_2$ in 100 grms. of soln. :

	- 21°	7°	11°	18°	38°	52°	64°	76°	89°	97°	105°
S .	52·1	56·5	57·0	59·1	62·7	64·2	68·2	70·1	69·7	69·2	70·2

do not show the transition temp. at 13°, but there appears to be one near 70°. A. Étard's data for manganous chloride also failed to show the transition temp. satisfactorily. There appears to be a stable or α-form of the tetrahydrate which, according to J. C. G. de Marignac, is isomorphous with the α-form of the tetrahydrated chloride, and it furnishes monoclinic plates with the axial ratios $a : b : c$ =1·1650 : 1 : 0·6483, and $\beta=99°\,6'$. There is also a labile or β-form of the tetrahydrate which is obtained in colourless rhombic plates by evaporating an aq. soln. of the bromide in a closed vessel. The β-form passes into the α-variety by mechanically stirring the mass ; and the transformation proceeds slowly when the crystals of the α-form are allowed to stand under their mother-liquor. The β-form has a lower decomposition temp., and a larger solubility than the α-form. A. Ferrari and F. Giorgi observed that the X-radiogram of the bromide, $MnBr_2$, corresponds with a lattice of the cadmium iodide type, having $a=3·820$ A., $c=6·188$ A. ; $a : c=1 : 1·62$; and density 4·549.

G. P. Baxter and M. A. Hines gave 4·385 for the sp. gr. of the anhydrous salt at 25°/4°. For A. Heydweiller's observations, *vide infra*. I. I. Saslawsky, and F. Ephraim and co-workers discussed the mol. vol., and the vol. contraction attending the formation of the salt from its elements. C. A. Valson studied the capillarity of the aq. soln. ; and S. Motylewsky found the drop-weight of the molten salt at its m.p. to be 78 when that of a drop of water at 0° is 100. J. B. Berthemot said that the tetrahydrate melts in its water of crystallization and then passes into the anhydrous salt ; and P. Kutznetzoff found that the m.p. of the tetrahydrate is 64·3°, at which temp. it passes into the monohydrate. C. J. Löwig, and A. Gorgeu observed that when the anhydrous salt is heated to redness in air, it loses bromine and passes into the tritatetroxide. H. Lescoeur found the vap. press. at 20° to be 5 mm. for the sat. soln. ; between 5·0 and 5·1 mm. for $MnBr_2,5·1H_2O$ to $MnBr_2$, $1·5H_2O$; and over 2·3 mm. for $MnBr_2,1·05H_2O$; at 100° the vap. press. of the sat. soln. is 202 mm., for the solid tetrahydrate 200 mm., and for $MnBr_2,1·1H_2O$ 50 mm. ; while at 150° the vap. press. for the hydrate between $MnBr_2,0·98H_2O$ and $MnBr_2,0·45H_2O$ is 98 to 99 mm., and for $MnBr_2,0·05H_2O$ 17 mm. A. Ferrari discussed some relations of the m.p. The vap. press., p mm., for the monohydrate is :

	20°	60°	100°	140°	150°	155°	160°
p .	5	40	200	56	99	122	156 mm.
	Saturated solution			Solid monohydrate			

J. Thomsen gave for the heat of formation, $(Mn,Br_2,Aq.)=106\cdot12$ Cals.; and M. Berthelot, $(Mn,Br_{2gas})=114\cdot4$ Cals., and $(Mn,Br_{2liquid},Aq.)=107\cdot0$ Cals. In the calculations M. Berthelot used the assumption that the heats of neutralization of manganous hydroxide by the three halide acids are the same. G. Beck discussed the free energy of formation; and G. Devoto and A. Guzzi found:

	700°	750°	800°	850°	900°
Free energy .	67,600	65,180	62,780	58,980	52,220 cals.

R. Robl observed no fluorescence in ultra-violet light. B. A. Isbekoff and W. A. Plotnikoff found the sp. electrical conductivity of a 15 per cent. soln. in molten aluminium bromide to be 0·001 at 160°. A. Heydweiller gave for the sp. gr. and eq. conductivity at 18°:

	0·5N-	N-	2N-	3N-	4N-
Sp. gr. . .	1·0447	1·0889	1·1763	1·2630	1·3491
λ . . .	72·4	64·7	53·54	(43·6)	35·64

W. Althammer gave for soln. with an eq. of the bromide in v litres, at 25°:

v . . .	20	40	80	160	320
λ . . .	100·4	106·1	111·5	116·6	120·3

A. Liebknecht and A. P. Wills gave for the magnetic susceptibility, of aq. soln. at 18°, 1×10^{-6} mass unit. G. Beck studied the energy of the salt. K. Jellinek and R. Ulroth found that no reaction between hydrogen and manganous bromide occurs below 770°, and that thereafter if $K=p_{H_2}p_{Br}/p^2_{HBr}$, then $\log K=-5223T^{-1}+0\cdot533 \log T-2\cdot72$. W. Ostwald found that manganous bromide has a slight stimulating effect on the reaction between bromic and hydriodic acids; J. B. Berthemot found that with conc. sulphuric acid, hydrogen bromide and bromine are formed. G. Gore, and E. C. Franklin and C. A. Kraus observed that the salt is insoluble in liquid ammonia, but F. Ephraim prepared **manganous hexamminobromide,** $MnBr_2.6NH_3$, by passing ammonia over the dehydrated salt; heat is evolved, and the solid swells up. The white ammine has the dissociation press., p mm.:

	83°	90°	104°	110°	114·5°	120°	124°	128°	130·5°
p .	86	127	240	308	370	468	550	650	720 mm.

W. Biltz and E. Birk studied the mol. vol. W. Biltz and G. F. Hüttig found that when manganous bromide is treated with ammonia gas as in the case of the chloride, similar ammines are produced (Fig. 78). For the hexammine, at 107°, the dis-
FIG. 78.—Dissociation Pressures of Manganous Hexamminobromide.
FIG. 79.—Dissociation Pressures of Manganous Decamminobromide.

sociation press., $p=305$, and the heat of dissociation, $Q=14\cdot26$ Cals.; for **manganous diamminobromide,** $MnBr_2.2NH_3$, at 182°, $p=13\cdot7$ mm., and $Q=20\cdot2$ Cals.; at 215°, $p=56\cdot4$ mm., and $Q=20\cdot4$ Cals.; and at 230°, $p=98\cdot0$ mm., and $Q=20\cdot5$ Cals. For **manganous monamminobromide,** $MnBr_2.NH_3$, at 215°, $p=12\cdot3$ mm., and $Q=21\cdot8$ Cals.; at 230°, $p=22\cdot9$ mm., and $Q=21\cdot95$ Cals.; and at 278°, $p=114$ mm., and $Q=22\cdot5$ Cals. F. Müller gave 20°–128° for the dissociation temp. of the hexamminobromide; 128° for the pentamminobromide; above 270° for the diamminobromide; and over 360° for the monamminobromide. F. Ephraim, and G. L. Clark also studied the hexammine. By working with man-

ganous bromide in a similar way to that employed for manganous chloride, W. Biltz and E. Rahlfs were able to prepare **manganous decamminobromide**, $MnBr_2.10NH_3$; which at $-78.5°$ had $p=27.5$ mm., and $Q=7.17$ Cals.; at $-70°$, $p=61.5$, and $Q=7.16$; at $-65°$, $p=95.0$, and $Q=7.16$; at $-60°$, $p=146.5$, and $Q=7.15$; and at $55°$, $p=146.5$, and $Q=7.16$—Fig. 79. F. Ephraim discussed the vol. contraction attending the formation of the ammines. H. Grossmann obtained a complex with pyridine, $MnBr_2.6C_5H_5N$; and R. J. Meyer and H. Best, $MnBr_2.2C_5H_5N$, and $MnBr_2.2C_5H_5N(HCl)$; A. R. Leeds, a complex with aniline, $MnBr_2.2C_6H_5(NH_2)$; A. Moitessier, with phenylhydrazine, $MnBr_2.2C_6H_5(NH.NH_2)$; G. A. Barbieri and F. Calzolari, with hexamethylenetetramine, $MnBr_2.2C_6H_{12}N_4.10H_2O$. F. Ducelliez and A. Raynaud obtained a complex with ether, $MnBr_2.(C_2H_5)_2O$; G. Spacu, one with diphenyl. M. Centnerszwer found that the salt is insoluble in liquid cyanogen.

According to F. Ephraim and S. Model, manganous bromide has *eine ausserordentlich geringe Neigung* to form complex salts, and in this respect it resembles cobaltous bromide. They were unable to prepare complex salts with the bromides of potassium, sodium, ammonium, barium, and strontium. By evaporating a mixed soln. of ammonium and manganous bromides they obtained what appeared to be isomorphous mixtures of ammonium bromide and **ammonium manganous tetrabromide**, $(NH_4)_2MnBr_4.H_2O$; while a soln. of sodium and manganous bromides furnished isomorphous mixtures of manganous bromide and **sodium manganous tribromide**, $NaMnBr_3.nH_2O$. No **potassium manganous bromide** could be obtained. C. E. Saunders observed that if a hot, sat. soln. of manganous chloride be treated with potassium bromide, and allowed to cool, there are deposited crystals of potassium manganous trichloride, containing variable amounts of probably the corresponding tribromide in isomorphous mixture; and similar results were obtained when an excess of potassium chloride is added to hot, sat. soln. of manganous bromide. There is no evidence to support the hypothesis that a mixed halide is formed. F. Ephraim and S. Model prepared **calcium manganous tetrabromide,** $CaMnBr_4.4H_2O$, in pink crystals, by evaporating a conc. soln. of the component salts over conc. sulphuric acid. The salt is a little hygroscopic, and it readily decomposes into its components. The corresponding *strontium and barium manganous tetrabromides* could not be prepared. C. E. Saunders obtained **magnesium manganous hexabromide**, $MgMn_2Br_6.12H_2O$, by evaporating a soln. of 2 mols of manganous bromide and one mol of magnesium bromide in 70 per cent. alcohol. The compact masses of red crystals deliquesce in air, and do not effloresce over calcium chloride; they lose 16.27 per cent. of water at $150°$; and the salt cannot be obtained by crystallizing the aq. soln. P. A. von Bonsdorff found that a sat. soln. of the component salts furnishes pale red columns of **mercuric manganous bromide,** which are very deliquescent. R. Varet gave for the heat of formation at $17°$ of $MnBr_2.2HgBr_2$, 2.92 Cals., and for $MnBr_2.HgBr_2$, 2.48 Cals. J. Kendall and co-workers obtained evidence of the formation of **aluminium manganous bromide,** $2AlBr_3.MnBr_2$; and B. A. Isbekoff and W. A. Plotnikoff observed that manganous bromide forms a yellow soln. with aluminium bromide, and the sp. conductivity of the 15 per cent. soln. is 0.001 mho at $160°$. B. Rayman and K. Preis obtained crystals of **manganous bromostannate,** or **stannic manganous hexabromide,** $MnSnBr_6.6H_2O$, in yellow, deliquescent crystals, by evaporating a soln. of the component salts. G. Spacu and J. Dick studied complexes of manganous and stannic bromides.

According to J. Nicklès, when one of the higher manganese oxides—Mn_3O_4, Mn_2O_3, or MnO_2—is treated with ether and hydrogen bromide, a green soln. is obtained which easily decomposes and which dissolves gold. By analogy with the corresponding chloride it was thought that *manganese tribromide*, or *manganese tetrabromide* is present; but R. J. Meyer and H. Best doubted if the ethereal or alcoholic soln. contains a higher manganese bromide, because when treated with pyridine hydrobromide it furnishes $MnBr_2.2C_5H_6NBr$. F. Ducelliez and A. Ray-

naud obtained a complex with ether, $MnBr_2.(C_2H_5)_2O$, of m.p. 65° to 70°. N. Bjerrum and G. H. Hansen could not prepare complexes with chromic bromide.

§ 20. Manganese Iodides

According to W. Peters,[1] the hydrated manganous iodide can be readily dehydrated in vacuo to form **manganous iodide**, MnI_2, as a pink, scaly mass; the salt must not be heated, since it begins to give off iodine at about 80°. According to F. Ducellicz, anhydrous manganese iodide can be readily obtained by the addition of iodine to finely-divided manganese covered with anhydrous ether. A vigorous reaction occurs, which is rendered complete by gentle warming on the water-bath. Excess of iodine and iodide of iron may be removed by washing the product with ether, whilst if an excess of manganese is employed, it can be separated from the precipitated iodide by washing away the latter in a stream of ether. A. Ferrari and F. Giorgi found that the anhydrous salt has the cadmium iodide structure, and that the X-radiograms correspond with a lattice having the parameters $a=4.16$ A., and $c=6.82$ A., and a sp. gr. 5.01. The aq. soln. of the salt was prepared by J. L. Lassaigne, J. C. G. de Marignac, and H. F. Gaultier de Claubry, by dissolving manganous carbonate in hydriodic acid. The soln. furnishes pink tabular crystals of the hydrated salt, and they have, according to J. L. Lassaigne, a styptic taste. P. Kutznetzoff observed that with soln. with a mol of MnI_2 in 8 mols of water, and cooled to $-20°$, crystals of the *enneahydrate*, $MnI_2.9H_2O$, are formed. These crystals are richer in water than the mother-liquor; and they melt at $-9.3°$. If the soln. sat. at 0° be cooled to $-5°$, deliquescent, prismatic, colourless plates of the *hexahydrate*, $MnI_2.6H_2O$, are formed; and at $-2.7°$ deliquescent pink plates of the *tetrahydrate*, $MnI_2.4H_2O$, are formed.

These crystals are stable at ordinary temp., and they are formed by the spontaneous evaporation of the aq. soln. H. Lescoeur found the vap. press. to be 83 mm. at 100° ; H. Lescoeur also reported the *dihydrate*, $MnI_2.2H_2O$, and the *monohydrate*, $MnI_2.H_2O$, to be formed by dehydrating the tetrahydrate. The dihydrate has a vap. press. of 47 mm. at 100° ; and the monohydrate, 180 mm. at 130°—but *vide supra* for the temp. of decomposition. A. Étard said that he made some observations on the solubility of the salt. F. Ephraim and co-workers discussed the mol. vol., and the vol. contraction attending the formation of the salt. C. A. Valson studied the capillarity of the soln. H. Lescoeur found the vap. press., p mm., of the mono-, di-, and tetrahydrates and of the sat. soln. to be :

		20°	50°	60°	66°	80°	100°	110°	120°	130°	133°
	H_2O	—	—	—	—	—	—	—	130	180	198
p	$2H_2O$	—	—	—	19	—	47	91	112	—	—
	$4H_2O$	—	—	5	—	—	34	83	135	—	—
	Soln.	3·5	7	13	—	—	42·5	104	154	210	—

He also found that at 20° the vap. press. of $MnI_2.6H_2O$ to $MnI_2.4·05H_2O$ is 3·6 to 3·8 mm., that of $MnI_2.3·98H_2O$ is over 1·7 mm. ; at 100° the vap. press. of $MnI_2.4H_2O$ to $MnI_2.3·02H_2O$ is 82 to 83 mm., that of $MnI_2.2H_2O$ to $MnI_2.1·4H_2O$ is 47 mm., and that of $MnI_2.0·98H_2O$, 25 mm. ; and at 130° the vap. press. of $MnI_2.0·98H_2O$ to $MnI_2.0·6H_2O$ is 179 to 180 mm., and that of $MnI_2.0·1H_2O$, 20 mm. A. Ferrari discussed the relation of the m.p. to the space-lattice. M. Berthelot found the heat of formation $(Mn,I_{2gas})=89·8$ Cals. ; and $(Mn,I_{2solid},Aq.)=76·2$ Cals. ; J. Thomsen gave $(Mn,I_{2solid},Aq.)=75·7$ Cals. F. Ephraim and O. Schütz discussed the heat of formation. G. Devoto and A. Guzzi gave for the free energy of formation :

	650°	700°	750°	800°	850°
Free energy	50,630	48,480	46,320	45,420	43,290 cals.

E. Wedekind found that the anhydrous salt is ferromagnetic ; and A. Liebknecht and A. P. Wills gave 49×10^{-6} mass unit for the magnetic susceptibility of aq. soln.

F. Ducelliez observed that manganous iodide is a white powder. J. C. G. de Marignac said that manganous iodide becomes brown on exposure to air ; and J. L. Lassaigne, and A. Gorgeu observed that if air be excluded, the salt can be melted without decomposition, but in air, iodine and manganese oxide are formed. W. Riedel found the eq. conductivity, λ, of a soln. of an eq. of manganous iodide in v litres, at 18°, to be :

v	20	40	80	160	320	640	1280	5120	∞
λ	101·13	105·89	111·09	115·18	119·94	112·37	123·55	127·32	130·6
a	0·7742	0·8108	0·8506	0·8819	0·9184	0·9370	0·9460	0·9750	100·0

The degrees of ionization, a, were also calculated ; and the transport numbers for $0·0025$ to $0·005M$-MnI_2 soln. were 0·6077 for the anion and 0·3923 for the cations ; and for a $0·05N$-soln. respectively 0·6232 and 0·3768. The H'-ion conc. of $0·05M$-MnI_2 is $10^{-4·45}$, and for $0·01M$-MnI_2, $10^{-4·54}$. This shows that the hydrolysis is very small. According to J. L. Lassaigne, the salt is very deliquescent. It is freely soluble in water, forming a colourless soln. which on evaporation yields white needles. The aq. soln. decomposes on exposure to air with the separation of brown flecks. P. Kutznetzoff found that when air is passed through a conc. soln. of manganous iodide or when a soln. is repeatedly evaporated, **manganous oxyiodide**, $MnI_2.MnO.6H_2O$, is formed in colourless, microscopic, birefringent needles, which gradually lose iodine at 115° to 120°. According to J. L. Lassaigne, iodine is liberated from manganous iodide by chlorine, and bromine, as well as by sulphuric acid. E. C. Franklin and C. A. Kraus found that the iodide is fairly soluble in liquid ammonia. W. Peters observed that the anhydrous salt absorbs ammonia to form **manganous hexamminoiodide**, $MnI_2.6NH_3$, and the white product loses a mol. of ammonia in vacuo. This is not taken up again when the salt is

re-exposed to the gas, so that some internal change occurs.   F. Ephraim gave for the dissociation press., p mm., of the hexammine :

	125·5°	135°	148·5°	149·5°	156°	162·5°	168·5°	173·5°
p .	105	150	225	280	364	475	596	720

W. Biltz and G. F. Hüttig prepared the hexamminoiodide as in the case of the hexamminochloride, Fig. 80.   There was no sign of the existence of a monammine. At 154° the dissociation press. of the hexamminoiodide $p=316$ mm., and the heat of dissociation $Q=16\cdot2$ Cals. ; and for **manganous diamminoiodide**, $MnI_2.2NH_3$, at 208°, $p=11\cdot1$ mm., and $Q=21\cdot6$ Cals. ; and at 215°, $p=14\cdot6$ mm., and $Q=21\cdot7$ Cals.   F. Müller gave 35° to 172° for the dissociation temp. of the hexammine ; 172° for the pentamminoiodide ; above 200° for the diammine and the monammine.
FIG. 80.—Dissociation Pressures of Manganous Hexamminoiodide.

F. Ephraim, and G. L. Clark discussed the vol. contraction attending the formation of the ammines ; and W. Biltz and E. Birk, the mol. vol.   J. L. Lassaigne found that nitric acid liberates iodine from manganous iodide.   P. Walden found manganous iodide to be soluble in phosphoryl chloride, and in arsenic iodide.   A. R. Leeds observed that with aniline, manganous iodide forms $MnI_2.2C_6H_5(NH_2)$; A.   Moitessier,   that   with   phenylhydrazine, MnI_2. $2C_6H_5.NH.NH_2$; and G. A. Barbieri and F. Calzolari, that with hexamethylenetetramine, $MnI_2.2C_6H_{12}N_4.10H_2O$ is formed ; B. Köhnlein found that manganous iodide and propyl chloride change their halogens at 145°–150°.   C. E. Saunders saturated a hot sat. soln. of manganous chloride with potassium iodide and observed that the precipitate, $KMnCl_3.2H_2O$, contained very little iodide ; and a similar result was obtained by treating manganous iodide with potassium chloride.   No evidence of the formation of a mixed potassium manganous chloroiodide was obtained. A. Duboin obtained a deposit of **mercuric manganous iodide**, $5HgI_2.3MnI_2.20H_2O$, from a sat. soln. of the component iodides evaporated over sulphuric acid at 17°.   The sp. gr. of the salt is 3·8.

J. L. Lassaigne observed that powdered pyrolusite with cold hydriodic acid forms a dark yellowish-red soln. which when warmed gives off iodine to form manganous iodide.   J. Nicklès found that if one of the higher manganese oxides be suspended in ether and treated with hydrogen iodide, a green liquid is formed which is easily decomposed.   Possibly these liquids contain a very unstable *manganese triiodide* or *tetraiodide*.   According to W. Riedel, **manganese tetraiodide**, MnI_4—probably $MnI_2.I_2$—exists in soln. obtained by shaking an aq. soln. of manganous iodide with iodine at 25°.   Just 2 mols. of iodine are taken up by $0\cdot1M$-MnI_2 ; more conc. soln. take up more iodine.   The eq. conductivity, λ, of the soln. of an eq. of the salt in v litres at 18° and the calculated degree of ionization, α, are :

v .	20	40	80	160	320	640	1280	5120	∞
λ .	85·09	89·99	94·66	99·02	102·61	106·34	108·81	111·59	114·39
α .	0·7478	0·7866	0·8274	0·8657	0·8970	0·9296	0·9511	0·9754	—

D. Dobroserdoff observed that when a mixed conc. soln. of manganous and mercuric iodides is heated on a water-bath and allowed to stand in a desiccator over sulphuric acid, yellow prisms of **manganous mercuric hexaiodide**, $Hg_2MnI_6.6H_2O$, are formed.   When roasted, manganese tritatetroxide is formed.   The salt is readily separated into its components in aq. soln., with the deposition of mercuric iodide. The salt dissolves without decomposition in acetone, and in alcohol.   A. Duboin obtained $3MnI_2.5HgI_2.20H_2O$ in an analogous way.   The sp. gr. of the salt is 3·8.   The salt dissolves freely, without decomposition, in methyl, propyl, iso-propyl, isobutyl, and allyl alcohols, in ethyl acetate and in ethyl cyanide ; it is rather less soluble in amyl, propyl, and isobutyl acetates, in acetone, in formic acid (with the precipitation of mercuric iodide), in acetic acid, in ethyl benzoate and oxalate, in butyl and amyl alcohols, and in nitrobenzene ; it is slightly soluble

with decomposition in glycerol; and it is insoluble in ethyl nitrate, ethylene bromide, toluene, benzene, chloroform, carbon tetrachloride, ethyl iodide, mono-bromobenzene, and monochlorobenzene.

§ 21. Manganese Sulphides

F. J. Müller von Reichenstein [1] described a mineral from Nagyag, Transylvania, which he called *Schwarze Blende*, and he regarded it as a Braunstein contaminated with sulphur; J. J. Bindheim also showed that it contained Braunstein, sulphur, iron, and silica; L. N. Vauquelin considered the manganese to be present in the lower stage of oxidation. A. M. del Rio described a Mexican mineral which he called *alabandina sulfurea*—after Alabanda in Caria, Asia Minor—and regarded as a compound of manganese, sulphur, and silica. D. L. G. Karsten called the mineral *Manganglanz*; C. C. Leonhard, *Braunsteinkies*; J. F. Blumenbach, *Braunsteinblende*; C. A. S. Hofmann, *Manganblende*; A. Breithaupt, *Blumen-bachite*; F. S. Beudant, *alabandin*; and J. D. Dana, **alabandite.** The analyses of J. A. Arfvedson, M. H. Klaproth, J. L. Proust, and A. F. Gehlen showed that the mineral is essentially **manganese monosulphide**, or **manganous sulphide**, MnS. Other analyses were reported by C. Bergemann, A. J. Moses, and A. Raimondi. Observations on the occurrence of the mineral in the Siebenbürgen were also made by P. Groth, M. J. Ackner, V. R. von Zepharovich, K. F. Peters, A. Schrauf, R. Zahrl, and E. von Fellenberg; in Hungary, by M. J. Ackner, V. R. von Zepharo-vich, A. E. von Reuss, P. Groth, R. von Vivenot, and B. von Cotta and E. von Fellenberg; in Saxony, by A. Breithaupt, and A. Frenzel; in France, by A. Lacroix, and A. Bertrand; in Brazil, by G. Leonhard; in Peru, by P. y Rico, and A. Rai-mondi; in Mexico, by C. Bergemann, H. J. Burkart, and A. M. del Rio; in the United States, by A. J. Moses, and W. B. Smith; and in New South Wales, by A. Liversidge. Manganous sulphide was reported to be a furnace product—*e.g.* in blast-furnace slags—by J. F. L. Hausmann, J. L. H. Vogt, and H. Vogelsang. F. Wüst reported that the sulphur in pig-iron containing manganese, becomes insoluble as manganous sulphide in the metal-bath. The good development of crystals of manganous sulphide shows that they existed while the mass was still fluid; in the words of H. le Chatelier and A. Ziegler:

Le sulfure de manganèse, avant pris une symétrie cristalline, est nécessairement l'élément de première consolidation, c'est-à-dire que son point de fusion est supérieur à celui du manganèse et par suite du fer; il est donc très éloigné de celui du sulfure de fer.

K. Jellinek and J. Zakowsky attempted to determine the affinity of manganese for sulphur. J. J. Berzelius converted the red hydrated sulphide, obtained by precipitation, into anhydrous manganous sulphide by heating it in a current of dry hydrogen sulphide; C. Doelter, P. de Clérmont, and T. Sidot used a similar process; and P. de Clérmont and H. Guyot dehydrated the green hydrated sulphide by heating it in dry hydrogen at 105°. Anhydrous manganous sulphide, in more or less well-defined crystals, was prepared by J. A. Arfvedson by passing hydrogen sulphide over heated manganous oxide or sulphate so long as water is formed. C. von Hauer, F. Fouqué and A. Michel-Lévy, and J. J. Ebelmen recommended a similar process, and E. von Fellenberg used manganous carbonate. H. Rose heated more or less oxidized manganous sulphide or sulphate mixed with sulphur in a current of hydrogen until the product had a constant weight; and J. A. Arfvedson also heated a mixture of pyrolusite or manganous carbonate and sulphur. G. Röhl heated a mixture of manganese oxide and an excess of sulphur to incandescence in a current of hydrogen and found the product contained 96·58 per cent. MnS, 1·94 per cent. Mn_3O_4, and 1·50 per cent. S. By repeating the operation on this product mixed with sulphur, only traces of oxide were contained in the resulting manganous sulphide. J. W. Döbereiner, and P. Berthier reduced the sulphate by carbon at a red-heat; K. Stammer reduced the sulphate by carbon monoxide; H. Rose, by hydrogen. A. Voelcker heated manganite to redness in a current of carbon disulphide vapour; and A. Gautier and L. Hallopeau observed that when the metal is similarly treated at 1400°, some carbide as well as sulphide is formed. R. Schneider obtained good crystals by melting a mixture of manganous sulphate, potassium carbonate, and sulphur (1 : 12 : 12), extracting the soluble salts with water, and drying the product in hydrogen. A. Mourlot reduced the sulphate by carbon in an electric furnace; M. Picon said that the product is always contaminated with carbide, and that sulphide of a high degree of purity is best made by the action of hydrogen sulphide on the oxide at 900°. J. Milbauer obtained the sulphide by fusing the oxide with potassium thiocyanate. E. Wedekind and T. Veit prepared the sulphide by the action of a manganese thermite mixture on sulphur; the action is very vigorous. H. de Sénarmont heated a soln. of a manganous salt with alkali sulphide in a bomb-tube at 187°; H. Baubigny left standing in a sealed tube for about a year a mixture of 1·1 grm. of neutral manganous acetate dissolved in 100 c.c. of water acidified with a few drops of acetic acid and saturated with hydrogen sulphide; and E. Weinschenk heated in a sealed tube at 230° to 250° an aq. soln. of a manganous salt, acetic acid, and ammonium thiocyanate. J. Milbauer obtained the amorphous sulphide by fusing a mixture of manganese oxide and potassium thiocyanate. E. Beutel and A. Kutzelnigg studied the anodic formation of the sulphide.

G. Bruni and M. Padoa found that manganous salt soln. in dil. hydrochloric acid gave no precipitate with hydrogen sulphide even when the gas is under a great press.; but if the soln. be treated with alkali sulphide or hydrosulphide, a precipitate is formed which, as J. F. John observed, may exhibit various colours— red, yellow, green, etc.—according to the conditions. According to V. M. Fischer, manganous sulphide may be precipitated from a faintly acid soln. of a manganous salt by means of hydrogen sulphide if the passage of the gas be sufficiently protracted. The precipitate obtained in this way is red or orange-red, and, depending on the degree of acidity of the soln., is either anhydrous or hydrated to a maximum of 17 per cent. of water, corresponding with the composition $MnS.H_2O$; under certain conditions it is deposited in the form of doubly refracting crystals. Rose-coloured manganese sulphide precipitated from a soln. of a manganous salt by means of the sulphide of an alkali metal is amorphous. The precipitate is usually flesh-coloured or pink, but if the soln. is much diluted, H. W. F. Wackenroder observed that the precipitate appears to be white for the first few moments. A. Villiers applied the term protomorphic to the condition or state in which various metal sulphides exist at the moment of their formation. The protomorphic state

is presumably equivalent to what is now called the colloidal state. O. Ruff and B. Hirsch discussed the precipitation of manganese sulphide in the presence of zinc, cadmium, and mercuric sulphides; and S. M. Kuzmeno, in the presence of zinc, iron, cobalt, and nickel sulphides. A. Terreil observed that in the presence of a large proportion of ammonium salts, the precipitate obtained with ammonium sulphide and a soln. of a manganous salt may be dirty yellow, and if much free ammonia is present, sulphur-yellow; and A. Voelcker, that a small, reddish precipitate may be produced if hydrogen sulphide is passed into a soln. of manganous acetate, particularly while the liquid is exposed to sunlight. These colorations may in part be due to impurities—sulphur, etc.—and in part to the degree of fineness of the precipitate. O. Ruff studied the precipitation in the presence of zinc salts.

Two main varieties are generally recognized, red or pink and green. The **red variety** is obtained when the precipitation is made under the conditions just indicated. U. Antony and P. Donnini recommended preparing the red sulphide by precipitation from ammoniacal soln. of manganous sulphate by ammonium sulphide, washing the product in an atm. of hydrogen sulphide, and drying it at 70° in a current of carbon dioxide. Any contamination with sulphur can be removed by washing the product with carbon disulphide. F. Seeligmann obtained it in an easily-filtered form by treating a soln. containing about half a gram per 200 c.c. with 10 to 20 c.c. of 25 per cent. ammonia per 10 c.c., heating the liquid to 60° to 80°, adding a slight excess of ammonium sulphide, and boiling for a few minutes. F. L. Hahn also described the preparation of the red sulphide. According to L. Joulin, equimolar parts of a soln. of manganous sulphate and sodium sulphide diluted 1 : 10,000, after standing four days, contain one-fifth of the sodium sulphide still undecomposed. C. R. Fresenius said that the precipitation is incomplete if colourless or yellow ammonium sulphide is employed; but if ammonium chloride be present, the precipitation is complete; A. Terreil, and A. Classen also observed that the presence of free ammonia hinders the precipitation of manganous sulphide by ammonium sulphide. H. How, J. Spiller, and C. R. Fresenius also observed that the presence of oxalic, tartaric, or citric acid hinders the precipitation of manganese sulphide by ammonia and ammonium sulphide; while the precipitation with alkali-lye and alkali sulphide is hindered by citric acid, but not by oxalic or tartaric acid. K. Jellinek and G. von Podjasky studied the reaction $MnS+2HCl$ $\rightleftharpoons MnCl_2+H_2S$—*vide supra*, manganous chloride; and O. F. Tower and E. E. Chapman, the formation of the sulphide in rhythmic rings.

According to C. R. Fresenius, the **green variety** of manganous sulphide can be obtained from the red in different ways. C. Meinecke obtained the green sulphide by treating an ammoniacal soln. of a manganous salt with ammonium sulphide, and boiling the mixture for some minutes. According to U. Antony and P. Donnini, if the washed precipitate of red sulphide be left in water, or better in a soln. of ammonium sulphide, for a few days, it turns green; and a similar change is brought about by heating the red powder to 300° to 320° in a current of carbon dioxide or hydrogen sulphide. J. C. Olsen and W. S. Rapalje obtained a similar result. J. T. Norton obtained the green sulphide by heating manganous sulphate with a soln. of sodium thiosulphate at 140° to 150°—the precipitation is incomplete. F. L. Hahn recommended the following process :

One hundred grams of manganese sulphate are dissolved in 300 c.c. of water. 100 c.c. of 20 per cent. ammonia soln. are sat. with hydrogen sulphide, and another 100 c.c. of the ammonia added (colourless ammonium sulphide). 30 c.c. of this liquid are saturated with sulphur at the boiling temp. and then made up to 100 c.c. with the colourless soln. (yellow ammonium sulphide). To a boiling mixture of 5 c.c. of the manganese soln., 20 c.c. of 20 per cent. ammonia, and 100 c.c. of water, are added 30 c.c. of the ammonium sulphide soln. The precipitated manganese sulphide is dark green. To this is immediately added the ammonium sulphide soln. and the warm manganese salt is added in portions, the mixture being kept almost boiling and well stirred. If the manganese salt is added too rapidly, the flesh-coloured sulphide separates ;

while V. M. Fischer recommended the following process :

Ten grams of tetrahydrated manganous chloride or a corresponding quantity of the sulphate are dissolved, together with 5 grms. of ammonium chloride, in 25 c.c. of water in an Erlenmeyer flask, 100 c.c. of 25–29 per cent. ammonia soln. being then added. From the clear soln. thus obtained, the rose-coloured manganese sulphide is precipitated by gradual addition from a dropping funnel of 100 c.c. of cold ammonium hydrogen sulphide, prepared by saturating 2·5 per cent. ammonia soln. with hydrogen sulphide ; during the precipitation the liquid is constantly shaken. After about fifteen minutes the rose-coloured precipitate begins to change into the green modification, the conversion being complete after some hours. The manganous sulphide is then separated by filtration, washed with dilute ammonium hydrogen sulphide soln., and dried in a current of hydrogen at 110°.

According to A. Mickwitz and G. Landesen, the sole condition for the formation of the green salt is the presence of free ammonia before the addition of the ammonium sulphide. If no free ammonia be present, the rose-coloured sulphide precipitated by ammonium hydrogen sulphide contains more sulphur than is required by the formula MnS, and its composition is better expressed by the formula $H_2Mn_3S_4$; in presence of free ammonia, the formula is $(NH_4)HMn_3S_4$, and this rose-coloured precipitate slowly passes into the green form, MnS, giving up $(NH_4)SH$ to the mother-liquor. P. de Clérmont and H. Guyot studied the conditions which influence the change. An excess of ammonium sulphide and heat favour the transformation ; while the presence of an excess of ammonium chloride hinders the change ; an excess of manganous salt or the use of sodium or potassium sulphide in different degrees of sulphuration gives the red sulphide. F. Muck found that solid manganous chloride gives some green salt in the cold ; the sulphate gives less ; the nitrate gives only traces ; the phosphate forms the green sulphide rapidly, so also does the oxalate. Ammonium sulphide precipitates the green sulphide from a hot ammoniacal soln. of manganous oxalate ; and a soln. of the red sulphide in ammonium oxalate gives the red sulphide when cold and the green sulphide when hot. According to P. de Clérmont and H. Guyot, the ammoniacal soln. of manganese oxalate with an excess of ammonium sulphide in the cold gives no precipitate, but when hot, red manganous sulphide separates and it quickly turns green. If a manganous salt be mixed for preference with potassium oxalate—ammonium oxalate and oxalic acid are less suitable —boiled, and treated with ammonia, and then with hot ammonium sulphide, a mixture of the red and green sulphides is formed, which when heated on a sand-bath becomes wholly green. This also occurs if ammonium chloride be present. F. Muck found that some green sulphide is produced when manganous carbonate is boiled for 10 mins. with ammonium sulphide in excess, and if heated for some hours in a sealed tube all is converted into the green sulphide, but the formation of green sulphide does not occur if the carbonate be gradually heated with soln. of hydrogen sulphide or of potassium or sodium sulphide. F. Muck, and P. de Clérmont and H. Guyot found that if the liquid in which the red sulphide is suspended be frozen, the green sulphide is formed, but A. Geuther said that this is not the case. A. Villiers obtained the green sulphide by adding a very small excess of ammonium sulphide to a very dil. soln. of manganous chloride at 0°. He said that the precipitation of manganous sulphide in a neutral soln. saturated with ammonium and alkali salts gives a pink precipitate which does not turn green, whereas precipitation in a neutral soln. containing but a small amount of foreign salts gives a pink sulphide which slowly changes at the ordinary temp. into the green form. In order to obtain the green sulphide in the cold, any excess of acid should be first removed, the soln. diluted, made alkaline with ammonia, and ammonium hydro-sulphide added. F. Muck observed that water or a conc. soln. of hydrogen sulphide or aq. ammonia does not transform the red into green sulphide when heated under ordinary press., or when heated to 140° or 150° in a sealed tube for 4 to 5 hrs., but P. de Clérmont and H. Guyot found that the transformation does not occur if the red sulphide is heated with water for 48 hrs., but a little is changed when it is heated in water vapour at 305°, and some red sulphide is changed by the soln. of hydrogen sulphide at 220° ; and with a 20 hrs.' heating with aq. ammonia at 220° the red sulphide is turned green, but not so

if ammonium chloride or quicklime be present. F. Muck observed that if the red sulphide be heated with an excess of ammonium sulphide at ordinary press., or at 140° to 150° in a sealed tube, the green sulphide is formed, but if the red sulphide be first heated with a little and then with an excess of ammonium sulphide it does not become green. P. de Clérmont and H. Guyot found that potassium and sodium sulphides do not change the red sulphide at ordinary press., or at a higher press. in a sealed tube, nor does the change occur if a little ammonium sulphide is present; potassium hydrosulphide under press. changes the red sulphide to a violet colour, and F. Muck obtained a similar result with potassium poly-sulphide. P. de Clérmont and H. Guyot observed that the red sulphide is not changed when heated to 300° with a soln. of ammonium sulphide; with ammonium carbonate, manganous carbonate is formed; with ammonium phosphate, man-ganous phosphate; and with potassium chloride, at 200°, a white compound. V. M. Fischer said that the change of red to green sulphide, which occurs in about 15 mins. in an ammoniacal soln. of ammonium sulphide in the presence of ammonium chloride, also takes place in absence of ammonium chloride, and for each con-centration of ammonia corresponding with the maximum velocity of the conversion. The latter is prevented by the presence of even a small proportion of hydroxylamine hydrochloride, and is retarded by ammonium chloride if this is added subsequently to the precipitation. The pink or red variety is also converted into the green form by trituration. The properties of the two sulphides were studied by H. B. Weiser and W. O. Milligan. They found that the change from the rose to the green manganese sulphide occurs at the b.p. in the presence of a sufficient excess of sodium sulphide. At room temp., the change readily occurs when ammonium sulphide in the presence of aq. ammonia is the precipitant. The critical conc. of the reagents for the maximum speed of the transformation is sharply defined. In the presence of ammonium hydrosulphide free from ammonia the change slowly occurs when the rose precipitate is seeded with the green one by mixing this form with the reactant before precipitation. Rapid mixing delays the change, and free ammonia is not essential. The solvent action of sodium sulphide and ammonium sulphide on the rose sulphide is an important factor in initiating and accelerating the transformation, but the absorption of ammonia by the rose precipitate acts protectively and retards the change. There is no evidence that the rose precipitate which spontaneously turns to green has the composition $(NH_4)HMn_3S_4$. The rose sulphides formed in the presence or absence of free ammonia are identical in structure, as are the light and dark green sulphides formed with sodium sulphide and ammonium sulphide respectively; the difference in colour is due to a variation in the size of the particle.

G. Landesen observed that the red precipitate obtained with a soln. of ammonium sulphide, free from ammonia, equivalent to 4·5 mols of NH_4HS per gram-atom of manganese acquires a greenish film in about 6 days, and that the subsequent change from red to green proceeds very slowly. There is, however, a more rapid change of red to orange, which is completed in about 6 months, and the dark green variety grows at the expense of the orange form. The passage from red to orange is accelerated in the presence of ammonia. The orange and red varieties are amorphous, the green form is crystalline. The reaction with manganous chloride is supposed to proceed $MnCl_2+NH_4OH \rightarrow Mn(OH)Cl+NH_4Cl$; followed by $Mn(OH)Cl+NH_4HS$ $\rightarrow Mn(OH)(HS)+NH_4Cl$; and by $Mn(OH)(HS) \rightarrow MnS+H_2O$. Likewise with the sulphate, $2MnSO_4+2NH_4OH \rightarrow HO-Mn-SO_4-Mn-OH+(NH_4)_2SO_4$; $HO-Mn-SO_4$ $-Mn-OH+2NH_4SH \rightarrow 2(HO.Mn.SH)+(NH_4)_2SO_4$; etc.

P. de Clérmont and H. Guyot found that the red sulphide after drying in vacuo contained water eq. to $MnS.H_2O$, and when dried in hydrogen at 105°, water eq. to $2MnS.H_2O$. C. R. Fresenius, and A. Classen said that the green sulphide is anhydrous; and E. Priwoznik found the green sulphide dried in vacuo has 13·39 per cent. of water, but when dried at 105° it is anhydrous. F. Muck regarded the green sulphide as an oxysulphide; and P. de Clérmont and H. Guyot observed that it

becomes anhydrous when heated in hydrogen at 105°, and it loses no more in weight when heated to redness in a current of carbon disulphide ; when the green sulphide has been dried in vacuo, it loses water eq. to $3MnS.2H_2O$, in dry hydrogen sulphide. J. C. Olsen and W. S. Rapalje said that the green and red sulphides are anhydrous ; and U. Antony and P. Donnini found that both the green and the red sulphides dried at 70° in a current of carbon disulphide have the same composition, being anhydrous manganous sulphides. The red variety consists of tiny, reddish, transparent crystals. U. Antony and P. Donnini, and J. C. Olsen and W. S. Rapalje said that the green variety is crystalline. According to V. M. Fischer, green manganous sulphide may be obtained either anhydrous or in a hydrated form, the content of water, which varies from 0 to 17 per cent. is dependent on the conc. of the ammonia, the presence or absence of ammonium chloride, and the length of time during which the precipitate remains in contact with the mother-liquor. Any hydrated green sulphide becomes anhydrous if left long enough in the liquid. This sulphide may be obtained crystalline if the soln. is stirred during the formation of the precipitate, or if ammonia is first added to the soln. of the manganous salt, and ammonium hydrogen sulphide then gradually introduced. P. de Clérmont and H. Guyot said that the green sulphide is stable, the pink variety unstable. The difference in the properties is not due to different degrees of hydration, for the transformation of the red to the green sulphide is not effected by dehydrating agents like potash-lye or alcohol, but it is effected by heating the red sulphide in a current of carbon dioxide under conditions where only 0·21 percentage loss in weight occurs. U. Antony and P. Donnini attributed the difference in coloration and chemical properties to differences in the state of condensation of the material, the green sulphide being more condensed than the red variety. This is because the sp. gr. of the green variety is rather higher than that of the red variety.

J. C. Olsen and W. S. Rapalje stated that in addition to the anhydrous red and green sulphides, there is a *grey variety* of manganous sulphide which is highly hydrated. The red sulphide of manganese obtained by the action of ammonium sulphide on a neutral soln. of manganous chloride appears to be a mixture of the grey and red sulphides in varying proportions. The red sulphide is not uniform in composition, and contains from 4 to 14 per cent. of free sulphur and a varying amount of water. The red variety of manganous sulphide is usually considered to be in the amorphous or colloidal state. O. Fisseler prepared **colloidal manganous sulphide** by adding the theoretical quantity of manganous sulphate to an aq. soln. of sodium lysalbinate or protalbinate, and, after adding some sodium hydroxide, passing a current of hydrogen sulphide through the liquor. The brown sol becomes flesh-coloured. The colloidal soln. when evaporated on a water-bath and dried in vacuo forms pale brown plates which readily form a sol with water. The sol is milky brown by reflected light and yellowish-brown with a reddish tinge in transmitted light. P. B. Ganguly and N. R. Dhar found that in colloidal soln. sulphur is formed. O. F. Tower and E. E. Chapman, and J. Hausmann observed that when manganous sulphide is precipitated in jellies, *rhythmic layers* may be formed.

Native manganous sulphide is iron-black or dark steel-grey. It usually occurs in granular aggregates ; it also occurs in cubic **crystals** with a cubic or dodecahedral habit ; there may be **twinning** about the (111)-face. R. W. G. Wyckoff discussed the possible space groupings for the X-radiogram of alabandite, and he concluded that the arrangement of the atoms with either 4 or 32 chemical molecules per unit cell is either that of the rock salt type or a tetrahedral or tetartohedral grouping very close to this. E. J. Cuy calculated 2·61 A. for the interatomic distance. H. B. Weiser and W. O. Milligan found the space-lattice is probably a face-centred cube with $a=5\cdot20$ A. The crystals were described by K. F. Peters, F. Roll, P. Groth, A. Breithaupt, E. von Fellenberg, R. von Vivenot, A. Schrauf, A. Bertrand, A. Lacroix, H. J. Burkart, A. J. Moses, W. B. Smith, etc. As indicated above, U. Antony and P. Donnini found both the red and green varieties

are crystalline, but others state that the red variety is amorphous. The crystals of the mineral alabandite are like those of sphalerite, or zinc-blende, but the minerals are not isomorphous because alabandite does not possess the dodecahedral **cleavage** of zinc-blende; rather is the cubic cleavage like that of sodium chloride and magnesium oxide. T. Sidot obtained yellowish-green hexagonal prisms isomorphous with wurtzite. Hence, like zinc sulphide, manganese sulphide is dimorphous. A. Damour, and A. des Cloizeaux observed a manganiferous variety of wurtzite in some lapis-lazuli from Siberia. They called it *erythrozincite*. Crystals of the alabandite type were obtained artificially by F. Fouqué and A. Michel-Lévy, C. Doelter, A. Reis and L. Zimmermann, H. Baubigny, E. Weinschenk, H. de Sénarmont, E. Wedekind and T. Veit, R. Schneider, and A. Mourlot—*vide supra*. V. M. Fischer said that the black crystals of the green sulphide have green streaks and have the form of octahedra or icositetrahedra. A. E. van Arkel found that the **X-radiogram** shows that ferrous and manganous sulphides form ionic space-lattices. H. Ott found that the space-lattice resembles that of manganous oxide with $a=5\cdot24$ A., and the calculated density is 3·98. O. Stelling, and W. F. de Jong and H. W. V. Willems studied this subject. O. Ruff examined the effect of copper and zinc sulphides on the space-lattice; and L. Royer, parallel growths of alkali halides on manganous sulphide. The **specific gravity** of the mineral given by V. R. von Zepharovich is 3·87; by R. Zahrl, 3·89; by H. J. Burkart, 4·125; by C. Bergemann, 4·036; and by A. J. Moses, 4·031 to 4·040. A. Mourlot found that the crystals obtained in the electric furnace have a sp. gr. 3·92, and that the sulphide which had been fused had a sp. gr. of 4·06. U. Antony and P. Donnini gave 3·55 at 17° for the sp. gr. of the anhydrous red sulphide dried at 70°, and 3·74 at 17° for the green sulphide. V. M. Fischer gave 4·03 for the sp. gr. of the crystals of the green sulphide; and 3·92 to 4·06 for the sp. gr. of alabandite. The **hardness** of alabandite is between 3 and 4. H. Fizeau found the coeff. of **thermal expansion**, a, to be 0·00001519 at 40°, and $da/d\theta=0\cdot07217$. A. Sella gave 0·1392 for the **specific heat**; and C. T. Anderson gave for the mol. ht., C_p:

	$-213\cdot2°$	$-103\cdot9°$	$-102\cdot9°$	$-57\cdot7°$	$0°$	$23\cdot9°$
C_p	5·068	7·467	11·36	11·43	11·80	11·93

The results for the whole series of observations are plotted in Fig. 81. There is a sharp maximum at about −135°, and a break in the curve at −126°. Manganous sulphide is not changed when heated out of contact with air; J. J. Berzelius observed that the red sulphide gives off water when heated in a retort—*i.e.* out of contact with air—and the green sulphide is formed. P. de Clérmont and H. Guyot observed that the red sulphide is not changed when heated in a closed vessel to 300°, and similarly with the green sulphide. N. Parravano and G. Malquori gave for the dissociation press. at 600°, log $p_{S_2}=-19\cdot62$. M. Picon said that manganous sulphide volatilizes unchanged at 1375°. G. Röhl observed that a sample of manganous sulphide containing 12·5 per cent.

FIG. 81.—The Molecular Heat of Manganous Sulphide.

of oxide melted at 1550°, while a preparation almost free from oxide had a **melting-point** of 1620°; J. H. Andrew and co-workers gave 1615°; and Z. Shibata gave 1610°; N. Parravano and P. de Cesaris gave for the **vapour pressure** at 800°, $4\cdot5\times10^{-18}$ atm.; at 900°, $8\cdot3\times10^{-16}$ atm.; at 1000°, $6\cdot6\times10^{-14}$ atm.; and at 1100°, $2\cdot8\times10^{-12}$ atm. J. Thomsen gave 46·37 Cals.; and C. T. Anderson gave 62·9 Cals. at 25° for the **heat of formation** of manganous sulphide from the metal and amorphous sulphur, and with rhombic sulphur, 44·39 Cals. M. Berthelot gave for precipitated manganous sulphide, $(Mn,S)=45\cdot6$ Cals., and also
$(H_2S_{soln.},Mn(OH)_{2precipitate})$=10·1 Cals., and J. Thomsen, 10·7 Cals. S. Wologdine and B. Penkievitsch gave 62·901 and 70·535 Cals. for the mol. ht. of formation of MnS. J. Thomsen gave $(Mn(OH)_2,H_2S,Aq.)$=10·7 Cals. ; M. Berthelot, 10·2 Cals. ; and J. Thomsen, $(Mn(NO_3)_2,H_2O,Aq.)$= −12·2 Cals.   J. Thomsen also gave $MnSO_4,400H_2O + Na_2S,400H_2O = Na_2SO_4aq. + MnS_{precipitate} + 7·79$ Cals. ; and $Mn(NO_3)_2aq.+H_2Saq.=MnS_{precipitate}+2HNO_3−12·26$ Cals. ; and M. Berthelot gave $Mn(C_2H_3O_2)_2aq.+Na_2Saq.=2NaC_2H_3O_2+MnS_{precipitate}+6·3$ Cals. C. T. Anderson gave − 64,000 cals. for the **free energy** of manganese sulphide ; and 18·7 for the **entropy** at 25°. G. Beck discussed the energy of formation. O. Stelling studied the X-ray spectrum. F. Beijerinck found the **electrical conductivity** of alabandite is negligibly small, cold or hot. W. Skey found the **electrochemical series** in sea-water to be −FeS, MnS, ZnS, SnS$_2$, HgS, Ag$_2$S, PbS, Cu$_2$S, FeS$_2$, Sb$_2$S$_3$+. E. T. Wherry observed that the crystals of alabandite make a fair **radio-detector**. E. Wedekind observed that when heated, manganous sulphide becomes strongly magnetic ; and E. Wedekind and C. Horst gave for the magnetic susceptibility of the sulphide $44·32×10^{-6}$ mass unit ; and G. Wistrand, $64·8×10^{-6}$.

A. Mourlot observed that the crystalline or fused sulphide is less chemically active than the amorphous. The sulphide is not attacked by **hydrogen** at 1200° ; but it is inflamed by **oxygen** below a red-heat. J. Milbauer and J. Tucek considered the roasting of the sulphide in **air** to be accompanied by the reaction : $R_mS_n+2nSO_2$ $=R_m(SO_4)_n+nS_2$. A. Mailfert observed that **ozone** slowly converts manganese sulphide into the peroxide, with the liberation of sulphuric acid ; and some permanganic acid is simultaneously formed. The artificial sulphide turns brown in air even at ordinary temp., but the mineral is not changed by exposure to air. O. Binder noted a tendency to ignition when the artificial sulphide is dried. H. Höfer, R. von Vivenot, and H. J. Burkart have observed the natural **weathering** of the mineral to the sulphate ; and E. von Fellenberg observed that the mineral is attacked by liquids ; and A. E. von Reuss, and E. Döll observed the change of the sulphide to carbonate. J. A. Arfvedson found that when the sulphide is ignited in air, it forms manganese tritatetroxide and sulphur dioxide, the native sulphide less readily than the artificial. P. de Clérmont and H. Guyot found that the red sulphide, when dried in vacuo, becomes red-hot when exposed to air and forms sulphur dioxide, manganous sulphate, and brown manganese oxide ; while the green sulphide is more resistant to oxidation. If 10 grms. of moist green sulphide be rubbed in a mortar, the temp. rises to about 60° and steam is given off. P. W. Hofmann observed that when the sulphide is heated a few minutes in a platinum capsule, sulphur dioxide is given off, and manganous sulphate, and manganese dioxide and monoxide are formed respectively in the proportions 44·5 : 18·9 : 36·6. W. Biltz found the **solubility** of manganous sulphide in **water** to be $1·10×10^{-4}$ mol per litre ; O. Weigel found that for the precipitated red sulphide the solubility is $7·16×10^{-5}$ mol per litre at 18°, and that for the green sulphide $5·45×10^{-5}$ mol per litre. It is here assumed that the sulphide is completely hydrolyzed to manganous hydroxide and hydrogen sulphide. L. Bruner and J. Zawadzky calculated the **solubility product** to be $1·4×10^{-15}$—the unreliability of this result turns on the uncertainty in the value for the potential of sulphur and manganese and on the state of the manganous sulphide in soln. The solubility product is probably higher than that of the sulphides of most heavy metals. This means that the conc. of the S″-ions is high in the presence of small H‴-ion concentrations, and hence the sulphide is soluble even in acids of feeble strength. I. M. Kolthoff discussed the subject. O. Ruff and B. Hirsch studied the joint precipitation of zinc and manganese sulphides. A. Voelcker said that the red sulphide turns litmus blue ; and P. de Clérmont and H. Guyot, that the red sulphide is decomposed when boiled with water. H. V. Regnault represented the reaction with steam at a red-heat by $3MnS+4H_2O=Mn_3O_4+3H_2S+H_2$.

According to A. Mourlot, the crystalline sulphide is not attacked by **fluorine** in the cold, but if heated below redness the sulphide is decomposed with incan-

descence, while at about 350° **chlorine** attacks the sulphide which has been crystallized in the electric furnace, and sulphur monochloride is formed. E. von Fellenberg found that when ordinary synthesized manganous sulphide is heated in chlorine, it is converted into sulphur monochloride and crystalline manganous chloride. H. Rose found that the mineral is only slightly attacked when heated in chlorine, and a little sulphur monochloride is formed. A. Mourlot found that **bromine** attacks the crystalline sulphide less readily than does chlorine; and that the attack by **iodine** begins at 600°. **Hydrofluoric acid** acts on the crystalline sulphide in the cold, and so does **hydrochloric acid**, but with **hydrobromic acid** the temp. must be raised, and so also with **hydriodic acid**. F. Feigl showed that the solubility of manganous sulphide in acid is due in part to the oxidation of the sulphide to hydroxide. H. W. F. Wackenroder found that the green sulphide readily dissolves in even weak **acids**, with the evolution of hydrogen sulphide and the formation of a manganous salt. According to H. W. F. Wackenroder, red manganous sulphide is slightly soluble in a soln. of **ammonium sulphide**, but not if **ammonium polysulphide** is present; consequently, if a soln. of a manganous salt be treated with an excess of ammonium sulphide, and the filtrate from the manganous sulphide be exposed to air, or treated with a little polysulphide, manganous sulphide is precipitated—*vide supra*. A. Classen said that manganous sulphide is slightly soluble in fused sodium sulphide. P. de Clérmont and H. Guyot found that the green sulphide is not altered when it is heated with a soln. of **hydrogen sulphide** in a sealed tube at 250°. H. W. F. Wackenroder, and P. Berthier found that red manganous sulphide dissolves in an aq. soln. of **sulphur dioxide**, forming, according to C. F. Rammelsberg, sulphur and manganous thiosulphate, and, according to L. Gmelin, some manganous sulphate, but no hydrogen sulphide is evolved; A. Guérout observed that if sulphurous acid is dropped on to red manganous sulphide, hydrogen sulphide is given off, and manganous sulphite and sulphur are formed: $MnS+H_2SO_3=H_2S+MnSO_3$, and a part of the sulphur reacts with the sulphite to form thiosulphate. For W. E. Henderson and H. B. Weiser's observations on the action of sulphur dioxide, *vide* **10.** 58, zinc metasulphate. J. Milbauer and J. Tucek observed that when sulphur dioxide is passed over the heated sulphide, some sulphate is formed, but at a higher temp. the sulphate is converted into oxide. F. Förster and J. Janitzky studied the action of sulphurous acid on manganese sulphide. L. Moser and M. Behr gave 0·0056 mol per litre for the solubility in a 0·01N-soln. of **sulphuric acid** at 20°.

Aq. **ammonia** colours manganous sulphide deep yellow, forming, according to F. Muck, no ammonium sulphide, but rather a polythionate. P. de Clérmont and H. Guyot found that the green sulphide is not changed by heating it in ammonia. L. Santi observed that manganous sulphide is attacked by soln. of ammonium chloride. P. de Clérmont and H. Guyot inferred that soln. of **ammonium salts** dissolve red manganous sulphide in accord with $MnS+4NH_4Cl=2NH_4Cl.MnCl_2$ $+2NH_3+H_2S$. The reaction begins in the cold, and 100 c.c. of a soln. of ammonium chloride, sat. at 12°, dissolve 0·43 grm. of MnS. The green sulphide is less soluble than the red. If the soln. in excess be boiled under conditions where the hydrogen sulphide and ammonia can escape, the manganous sulphide all passes into soln.; but in a sealed tube a balanced reaction is set up. If ammonium sulphate be employed, polythionates may be found—for instance, F. Muck observed the formation of trithionate.

According to C. Tissier, a hot soln. of **boric acid** dissolves red manganous sulphide. L. Kahlenberg and W. J. Trautmann observed no reaction when a mixture of powdered silicon and the sulphide is heated over the bunsen burner, but at a higher temp. a reaction occurs. A. Mourlot found that manganese sulphide, unlike the sulphides of iron, cobalt, nickel, and chromium, is not attacked by **carbon** heated in the electric furnace for 15 mins. M. Houdard found that the diamond as well as amorphous carbon dissolves to the extent of 3·2 per cent. in molten manganous sulphide, and on cooling the carbon is rejected as graphite. M. Picon said that the

heated sulphide can dissolve 15 per cent. of graphite without apparent change. N. Parravano and G. Malquori gave for the reaction $2MnS+C=2Mn+CS_2$, at 1500°, $\log p_{CS_2} = -4.923$. A. Wagner said that moist **carbon dioxide** rapidly attacks red manganous sulphide, liberating hydrogen sulphide, and, added P. de Clérmont and H. Guyot, the action is rapid if the temp. is raised. The red sulphide liberates hydrogen sulphide when it is treated with **acetic acid.** F. W. O. de Coninck found that **glycol** dissolves 5 per cent. of the red sulphide ; and A. Naumann, that the sulphide is insoluble in **acetone.**

P. de Clérmont and H. Guyot observed that **sodium** amalgam and water do not attack the green sulphide, but do attack the red sulphide. C. H. Herty and O. S. True, and G. Röhl studied the reversible reaction with **iron,** $Fe+2MnS \rightleftharpoons 2Mn +FeS_2$, and the formation of a complex salt, FeS.MnS. H. W. F. Wackenroder, and F. Muck observed that white manganous hydroxide is formed by a boiling soln. of **potassium hydroxide ;** and P. de Clérmont and H. Guyot, by an alcoholic soln. of potassium hydroxide in a sealed tube at 150°. P. Berthier found that an excess of molten **lead oxide** forms sulphur dioxide, lead, and a slag containing lead and manganous oxides. A. Gorgeu found that manganous sulphide reacts with many **metal salt** soln., forming the metal sulphide and a manganous salt—*e.g.* E. F. Anthon observed that manganous sulphide decomposes soln. of copper and cadmium sulphates ; silver, cobalt, and nickel nitrates: lead acetate, and ferric chloride ; and E. Schürmann, soln. of ferrous and nickel sulphates and thallous and cobalt nitrates. According to E. Diepschlag and E. Horn, the reaction between **ferric oxide** and manganese sulphide begins at about 550°, and at 800° to 850° the reaction $MnS+9Fe_2O_3=MnO+6Fe_3O_4+SO_2$ is completed ; the reduction of the ferrosic oxide begins at about 950°, and at 1250° the reaction is $MnS+3Fe_3O_4 =MnO+9FeO+SO_2$. No compound, $MnO.Fe_2O_3$, was observed. They also studied the action of the sulphide on **ferrous oxide,** and on **ferrosic oxide**—*vide* iron. J. H. Andrew and co-workers studied the system with manganese sulphide and **manganese silicate** and with **ferrous silicate.** In the former, there is a eutectic at 1250° and 10 per cent. MnS ; and in the latter, one at 1055° and 10 per cent. MnS.

J. A. Arfvedson reported **manganous oxysulphide,** MnO.MnS, to be formed by heating manganous sulphate in a current of hydrogen ; K. Stammer used carbon monoxide as the reducing agent. The pale green powder is stable in air when cold, but when heated it burns to manganosic oxide ; it forms manganous sulphide when heated in hydrogen sulphide ; and it dissolves in acids, giving off hydrogen sulphide. J. Landauer said that when a manganese compound is fused with sodium thiosulphate, a cake coloured pale green by manganous oxysulphide is formed. According to V. M. Fischer, in the presence of a large excess of sodium hydroxide, the addition of sodium sulphide to a soln. of a manganese salt gives not the rosecoloured sulphide, but a white precipitate of **manganous hexahydroxysulphide,** MnS.3Mn(OH)₂, or HO.Mn.O.Mn.S.Mn.O.Mn.OH. J. H. Andrew and co-workers studied the system MnO—MnS and found it to have a simple eutectic at 1285° with 50 per cent. MnS. There were limited solubilities at both ends of the curves.

P. Berthier obtained a pale brownish-red mass of **sodium manganous heptasulphide,** $2Na_2S.5MnS$, by heating white hot a mixture of manganous sulphate and sodium sulphate (10 : 5) in a carbon crucible. A. Voelcker prepared **sodium manganous tetrasulphide,** $Na_2S.3MnS$, by melting a mixture of dry manganous sulphate, lamp-black, and sodium carbonate (5 : 1 : 15), and, after cooling, washing out the sodium sulphide with alcohol, and the sodium sulphate by air-free water. The mass is exposed to air as little as possible during the washing operations ; and the pale red, acicular crystals are pressed between bibulous paper and dried in vacuo. The dry salt is stable in dry air, but when moist it is very readily oxidized, with the development of heat, and sometimes with inflammation. When heated on platinum foil it burns to sulphur dioxide, sodium sulphate, and manganic oxide. It is insoluble in water, alcohol, and ether ; it is freely soluble in dil. acids, with the

development of hydrogen sulphide ; and with sulphurous acid sulphur is separated and manganous thiosulphate is formed. A. Voelcker prepared **potassium manganous tetrasulphide,** $K_2S.3MnS$, in dark red plates by the method which he employed for the sodium salt. It behaves very like the sodium salt, being readily oxidized in moist air, and readily burning when heated. A mixture of the salt with potassium nitrate detonates vigorously. It is insoluble in water, alcohol, and ether ; it is gradually decomposed by water with dissolved air, forming soluble potassium sulphide, sulphate, and thiosulphate, and insoluble sulphur, and hydrated manganic oxide. It is easily dissolved by acids—even acetic acid—with the liberation of hydrogen sulphide. J. Meyer and H. Bratke prepared the same salt. J. Milbauer obtained flesh-coloured crystals of a complex salt by the action of potassium thiocyanate on manganosic oxide at a bright red-heat. R. Schneider obtained **potassium manganous trisulphide,** $K_2S.2MnS$, by heating a mixture of manganous sulphate, potassium carbonate, and sulphur (1 : 6 : 6) along with crystals of manganous sulphide. The crystals of the two salts can be separated by levigation. R. Schneider fused at a red-heat a mixture of dry manganous sulphate, sodium carbonate, and sulphur (1 : 6 : 6), washing the cold product with air-free water, pressing between folds of bibulous paper, and drying in vacuo over conc. sulphuric acid, and obtained flesh-coloured plates and needles of **sodium manganous trisulphide,** $Na_2S.2MnS$. The moist product readily oxidizes ; and it is gradually decomposed by water. J. Milbauer obtained the complex salt, on one occasion, by fusing manganous oxide with potassium thiocyanate. According to W. Guertler and K. L. Meissner, on melting a mixture of *manganese and copper sulphides,* the mass separates into two layers, the upper consisting of manganese sulphide or of a eutectic of manganese and cuprous sulphides and the lower of pure copper or of mixed crystals of copper and manganese, according to the proportions of both metals present. Manganese has, therefore, a greater affinity for sulphur than copper, and this affinity is not modified by the addition of iron. Thus, if iron is added to a mixture of molecular proportions of cuprous sulphide with 1 atomic proportion of manganese, the mass separates into three layers, an upper layer of manganese sulphide, a middle layer of a eutectic mixture of manganese sulphide and iron, and a lower layer of copper more or less mixed with iron. W. Guertler discussed the formation of **copper manganese sulphide** in the ternary system Cu–Mn–S. According to M. Houdard, **aluminium manganous sulphide,** $Al_2S_3.MnS$, is produced when a mixture of aluminium turnings and manganese sulphide contained in a carbon boat placed in a porcelain tube is heated to dull redness for an hour in a current of hydrogen sulphide, and then the temp. is raised to a white-heat for half an hour. The product is attacked by cold water, with evolution of hydrogen sulphide and deposition of aluminium hydroxide, but the greater part, composed of brownish-yellow crystals, is insoluble. The latter is powdered and treated with acetic acid to remove aluminium sulphide. If the original mixture contains excess of manganous sulphide, the product consists of a pale golden-yellow mass throughout which green crystals of manganese sulphide are disseminated.

J. B. Hannay [2] reported a doubtful mineral which he called *plumbomanganite.* The analysis corresponded with $3MnS.PbS$, or *lead manganous tetrasulphide.* The sp. gr. was 4·01. He also obtained other doubtful minerals called *youngite*—after J. Young—representing *zinc lead manganous sulphide,* one corresponding with $6ZnS.PbS.MnS$ from the Harz ; another with $24ZnS.5PbS.5MnS$; and yet another with $10ZnS.3(MnS,FeS).2PbS$, from Ballarat, Australia. The sp. gr. ranged from 3·59 to 4·56.

A. Gautier and L. Hallopeau [3] heated rhodonite, $MnSiO_3$, in a current of the vapour of carbon disulphide at a white-heat, and obtained **manganosic sulphide,** or **manganese tritatetrasulphide,** Mn_3S_4, as an easily pulverized mass. Unlike manganous sulphide, it is easily hydrolyzed by water, with the evolution of hydrogen sulphide.

W. Haidinger described a reddish-brown or brownish-black mineral from

Kalinka, Hungary. It was discovered by K. Adler in 1846, and W. Haidinger called it **hauerite**—after J. and F. von Hauer. Analyses reported by W. Haidinger, E. Scacchi, A. Silvestri, M. Matzke, and H. de Sénarmont agree with the formula for **manganese disulphide**, MnS_2; and from the analogy with iron pyrites, P. Groth called it *manganese pyrites—Mangankies*. The Hungarian deposit was also described by L. von Cseh; Silician deposits were described by E. Scacchi, A. Silvestri, and F. de Memme; and a New Zealand deposit by S. H. Cox. H. de Sénarmont obtained manganese disulphide as an amorphous, brick-red powder, by warming a soln. of manganese sulphate and potassium polysulphide in a sealed tube at 160°. C. Doelter heated a mixture of manganese dioxide and sulphur in a current of hydrogen sulphide, and obtained crystals of artificial hauerite mixed with those of alabandite. According to L. von Cseh, the hauerite of Kalinka has been formed by solfateric action in which the vapours of sulphuric acid, hydrogen sulphide, and steam have acted on the pyroxene trachytes of that district. The deposits in the Gulf Coast salt domes were studied by A. G. Wolf, and M. A. Hanna.

Hauerite sometimes occurs in reddish-brown or brownish-black pyritohedral, cubic **crystals,** commonly in octahedra, but sometimes in globular clusters. The octahedral crystals were described by E. Onorato. The powdered mineral is brownish-red. The cubic **cleavage** is imperfect. W. H. and W. L. Bragg, P. P. Ewald and W. Friedrich, and A. E. van Arkel said that the **X-radiograms** of crystals of hauerite show that the structure is the same as those of pyrites and of cobaltite. R. W. G. Wyckoff discussed the possible groupings of atoms of manganese and sulphur in the space-lattice to form cubic crystals; $a=6\cdot111\times10^{-8}$ cm. E. J. Cuy gave 2·59 A. for the interatomic distance. P. Niggli studied the **electronic structure.** The crystals were discussed by W. Haidinger, W. H. Miller, V. Goldschmidt and K. Schröder, A. G. Wolf, and E. Scacchi, A. Silvestri, and F. de Memme. W. Haidinger gave 3·463 for the **specific gravity;** E. Scacchi, 3·366 to 3·411; A. G. Wolf, 3·49; and A. Silvestri, 3·50 to 3·71. The **hardness** is about 4. H. Fizeau found the coeff. of **thermal expansion** to be $a=0\cdot00001111$ at 40°; and $da/d\theta=0\cdot0_{7}889$ per degree. G. Spezia observed that when hauerite is heated, it begins to lose sulphur at about 170°, and is ultimately converted into manganous sulphide. J. Joly said that a sublimate is formed at 450°. T. W. Case observed no cleavage in the electrical conductivity on exposing hauerite to light. R. D. Harvey, and F. Beijerinck made some indecisive observations on the **electrical conductivity** of hauerite.

According to A. Beutell and M. Matzke, when hauerite is shaken with water and **air,** a soln. of sodium carbonate, or a soln. of sodium acetate and acetic acid, it is oxidized, with the separation of free sulphur, but no sulphuric acid is formed. In this respect the mineral differs from pyrites, and it is therefore assumed that hauerite does not belong to the pyritic family of minerals—*vide supra*. M. Matzke also found that with **hydrogen dioxide** the whole of the sulphur separates as elemental sulphur. Unlike pyrite and marcasite, hauerite colours red litmus paper blue. It reacts with **hydrochloric acid,** liberating half the sulphur in the elemental form and half as hydrogen sulphide: $MnS_2+2HCl=MnCl_2+H_2S+S$. Here again hauerite behaves differently from pyrite and marcasite. According to G. Spezia, hauerite forms an explosive mixture with **potassium chlorate,** but does not react with it in the presence of water even at 100°. J. Strüver found that when crystals of hauerite are in contact with **silver,** there is slowly formed about that zone a dark film of silver sulphide: $4Ag+MnS_2=Mn+2Ag_2S$; if copper is in contact with the silver, the reaction is accelerated; **copper** in contact with hauerite also forms copper sulphide. Marcasite, pyrite, magnetic pyrites, cobaltite, and iron arsenide also react similarly with copper and silver; but not so with stibnite. The strongest reaction occurs with sulphur alone. Hauerite, pyrite, and marcasite do not give the reaction with the **metals** zinc, tin, lead, antimony, bismuth, iron, nickel, and platinum. E. Arbeiter, and A. Beutell investigated the reaction with silver. They found that the reaction takes place without contact up to a distance of 1 cm., for

sulphur is perceptibly volatile at ordinary temp. He concluded (i) that when hauerite is oxidized in air, free sulphur is formed—a similar result was obtained with arsenical pyrites, pyrite, marcasite, glaucodote, and cobaltite ; (ii) that the action of hauerite on silver is caused by free sulphur ; (iii) that the free sulphur can be distilled from the mineral in vacuo at 56° to 60°, and it becomes inactive. The activity is regained after the mineral has been re-exposed to air for 24 hrs. E. Quercigh agreed that the effect may in part be due to the vapour of sulphur produced by the decomposition of hauerite in air ; but the action may be produced when the mineral and the metal are pressed together under toluene, under conditions when it can be due neither to sulphur nor to hydrogen sulphide in the hauerite, nor to the removal of the sulphur from the mineral by toluene. He agreed with J. Strüver that the action is due to the passage of the combined sulphur of the hauerite directly to the silver or copper with which the mineral is in contact.

§ 22. Manganous Sulphate

C. W. Scheele [1] prepared **manganous sulphate**, $MnSO_4$, and distinguished it from all other salts. J. H. Pott, and C. F. G. H. Westfeld previously obtained the salt and confused it with alum, so that alumina was regarded as a constituent of pyrolusite. J. C. Ilsemann, and J. C. Schmeisser also confused manganous sulphate with magnesium sulphate, so that magnesia was regarded as a constituent of pyrolusite. In these cases, manganous sulphate was prepared from the soln. obtained by digesting pyrolusite with sulphuric acid. J. F. John [2] obtained a soln. of manganous sulphate by dissolving the metal in dil. sulphuric acid. It is also obtained by the action of hot sulphuric acid on manganese oxides, manganous carbonate, etc. Thus a soln. of the salt is obtained by boiling pyrolusite with dil. sulphuric acid to remove calcareous and magnesian impurities, heating the product with conc. sulphuric acid, evaporating to dryness, and gently igniting the resulting product to decompose the copper and iron sulphates. The undecomposed manganous sulphate is washed out with water. If any copper or iron salt is still present in soln., the former can be removed by hydrogen sulphide, and the latter by digesting the soln. with manganous carbonate. A. Gorgeu, A. Barreswil, G. Kassner, and F. Muck used modifications of this process. J. Milbauer obtained the sulphate by heating a mixture of pyrolusite and ferrous sulphate at 700°. If the operation be conducted in an open furnace, serious losses of sulphur trioxide occur. N. W. Fischer, and C. Klauer heated a mixture of pyrolusite and ferrous sulphate—say 1 : 4—and extracted the cold product with water to remove the manganous sulphate. C. Brunner heated a mixture of pyrolusite, sulphur, and wood-charcoal (10 : 4 : 1) for 2 hrs. ; treated the mass with dil. sulphuric acid ; extracted the soluble matter with water ; evaporated to dryness the filtrate with a little nitric acid ; heated the product to dull redness ; extracted the mass with water ; treated the filtrate with calcium carbonate in the cold ; and evaporated the filtrate—calcium sulphate first separates out, and afterwards crystals of hydrated manganous sulphate. The pentahydrate usually crystallizes from aq. soln. at ordinary temp. For R. de Forcrand's polymerides, *vide infra*.

Observations on the **solubility** of manganous sulphate were made by R. Brandes, F. Jahn, C. von Hauer, G. J. Mulder, C. E. Linebarger, etc. According to A. Étard, the solubility in water increases from 0° to about 55°, and decreases from about 55° to 145°. The increasing solubility is that of the pentahydrate ; the dihydrate separates out at 35°, and is completely insoluble at 145°. If S denotes the percentage amount of $MnSO_4$ in the soln., at $\theta°$, between −8° and 57°, $S = 30 \cdot 0 + 0 \cdot 2828\theta$; and between 57° and 150°, $S = 48 \cdot 0 - 0 \cdot 4585\theta$. F. Rüdorff gave for the percentage solubility at −3·35°, $S = 19 \cdot 4$, and at −7·50°, $S = 27 \cdot 9$. C. E. Linebarger gave results in great detail, but other observers have shown that something is wrong with them. F. G. Cottrell found the **eutectic temperature** is nearly 10·5° for $S = 32 \cdot 2$, when the solid phases are ice and the heptahydrate. He found that

the four hydrates—mono-, tetra-, penta-, and heptahydrates—can exist in aq. soln.; and that the solubility of manganous sulphate at different temp. is as follows :

	−10°	0°	9°	15°	20°	27°	30°	50°	70°	100°
S .	32·4	34·7	37·2	37·9	38·6	39·8	39·4	37·3	34·2	24·9
Solid phase		7H₂O			5H₂O			H₂O		

These results are plotted in Fig. 82. F. Flöttmann found the solubility of the pentahydrate at 15°, 20°, and 25° to be respectively 3·703, 3·800 and 3·927 mols per litre, or 37·85, 38·59, and 39·554 per cent.

FIG. 82.—The Solubility of Manganous Sulphate in Water.

A. Étard added that at 140°, $S=9·5$, and at 180° and 200°, S is nearly zero. According to F. G. Cottrell, there is also the unstable or labile monohydrate with a percentage solubility of 40·3 at 20°. There is also the unstable or labile tetrahydrate with a percentage solubility of 38·8 at the transition temp., 14°, between the hepta- and tetrahydrate; and 40·80 at 40°. T. W. Richards and F. R. Fraprie gave 39·89 and 40·56 for the solubilities of the unstable tetrahydrate respectively at 30·15° and 35·00°. For R. M. Caven and W. Johnston's observations, vide infra, sodium manganese sulphate.

When hydrated manganous sulphate is heated to redness it forms the anhydrous salt; T. E. Thorpe and J. I. Watts found that the anhydrous salt is formed when the hydrate is heated to 280°. J. H. Krepelka and B. Réjha found that the salt is anhydrous at 450°; and J. G. F. Druce obtained the anhydrous salt by heating the hydrate in nitrobenzene boiling at 207°; but not in xylene boiling at 140°. Analyses in agreement with $MnSO_4$ were reported by R. Brandes, E. Turner, G. Forchhammer, and C. von Hauer. C. E. Linebarger said that the anhydrous salt is the solid phase in the presence of an aq. soln. of the salt above 117°; but there is something wrong, because A. Étard observed that at 180° the solubility of the salt is almost zero, and that the solid phase is a pale pink, porcelain-like mass of the **monohydrate**, $MnSO_4.H_2O$. For R. de Forcrand's polymerides, vide infra. J. H. Krepelka and B. Réjha found that the monohydrate is stable up to nearly 200°. J. G. F. Druce obtained the monohydrate by heating the salt with toluene boiling at 110°. O. B. Kühn obtained a reddish-yellow, pulverulent deposit of the monohydrate by rapidly boiling an acidic soln. of manganous sulphate, and T. Graham, by similarly treating a neutral soln., or by drying the pentahydrate at 194° to 210°; E. S. Larsen and M. L. Glenn, by evaporating a soln. of the sulphate on a steam-bath; O. Pettersson, by drying the pentahydrate at 150°, and T. E. Thorpe and J. I. Watts, by drying it at 100°—vide Fig. 82. Analyses were reported by T. Graham, O. B. Kühn, and H. Lescoeur. According to J. von Schröckinger, reddish-white or rose-red, amorphous, stalactitic masses of the monohydrate occur as a mineral in Felsöbanya, Hungary. He called the mineral **szmikite**—after B. Szmik. The dihydrate, $MnSO_4.2H_2O$, does not appear as a solid phase on the solubility curve, Fig. 82. The results of W. Müller-Erzbach, and H. Bolte (Fig. 82) agreed with the existence of a dihydrate; but W. Schieber said that it is not a chemical individual. R. Brandes said that he obtained it by melting the heptahydrate, or by boiling the hydrated salt with alcohol. T. E. Thorpe and J. I. Watts, J. Thomsen, and T. Graham used similar processes. For R. de Forcrand's polymerides, vide infra. R. Brandes reported the trihydrate, $MnSO_4$. $3H_2O$, to be deposited from a warm aq. soln.; also by evaporating a soln. of the tetrahydrate in vacuo over sulphuric acid; and by exposing the anhydrous
salt in air. The trihydrate was also described by T. Graham, J. Thomsen, and T. E. Thorpe and J. I. Watts, but it does not appear as a solid phase on the solubility curve, Fig. 82, and W. Schieber denied its existence ; R. de Forcrand was unable to prove its existence. According to H. V. Regnault, the **tetrahydrate,** $MnSO_4.4H_2O$, is formed by crystallization from an aq. soln. of manganous sulphate at a gentle heat—between 20° and 30° ; or, according to J. C. G. de Marignac, between 30° and 40°. E. S. Larsen and M. L. Glenn said that the tetrahydrate is obtained by evaporating a soln. of the sulphate at 45° under reduced press. The tetrahydrate of the earlier observers—H. Kopp, G. T. Gerlach, G. J. Mulder, R. Brandes, J. F. John, E. Mitscherlich, and J. Thomsen—was possibly the overdried pentahydrate, because the observations of T. W. Richards and F. R. Fraprie, and F. G. Cottrell show that it is an unstable hydrate (Fig. 82), and that the transition temp. of $MnSO_4.7H_2O \rightleftharpoons MnSO_4.4H_2O + 3H_2O$ is nearly 14°. R. de Forcrand also prepared this salt. H. V. Regnault observed that the **pentahydrate,** $MnSO_4.5H_2O$, or *manganese vitriol*, is formed by evaporating an aq. soln. between 7° and 20° ; and J. C. G. de Marignac, by evaporating it between 15° and 20°. A. Carnot obtained it by crystallizing the aq. soln. at 15°. E. S. Larsen and M. L. Glenn obtained the pentahydrate by evaporating a soln. of the sulphate at 23° under reduced press. They call the triclinic minerals of the general formula $R_2SO_4.5H_2O$ *chalcanthites*, and describe zinc-copper-chalcanthite, iron-copper-chalcanthite, cobalt-chalcanthite, and manganese-chalcanthite. The artificial crystals are biaxial, and the indices of refraction are $\alpha = 1.495$, $\beta = 1.508$, and $\gamma = 1.514$. The optical axial angle $2V$ is large ; the optical character negative ; and the dispersion is slight. R. Brandes made the pentahydrate by allowing the heptahydrate to stand in contact with cold alcohol ; and E. Classen, R. de Forcrand, E. Mitscherlich, and H. V. Regnault, by adding alcohol to a sat. aq. soln. of manganous sulphate and allowing the syrupy liquid to crystallize. The salt was also prepared by O. Pettersson, J. Thomsen, T. Graham, etc. The range of its stability in the presence of its aq. soln. is illustrated by Fig. 82 ; and the transition temp. of $MnSO_4.7H_2O \rightleftharpoons MnSO_4.5H_2O + 2H_2O$ is nearly 9° ; and the transition temp. of $MnSO_4.5H_2O \rightleftharpoons MnSO_4.H_2O + 4H_2O$ is nearly 27°. C. E. Linebarger said that the pentahydrate can exist over the range of temp. 8° to 18°, and that a *hexahydrate*, $MnSO_4.6H_2O$, can exist over a temp. range of —5° to 8° ; but this has not been verified, and W. Schieber denied its existence, and R. de Forcrand was unable to make it, although isomorphous mixtures with hexahydrated zinc sulphate are known (Fig. 82). R. Brandes, and H. V. Regnault obtained the **heptahydrate,** $MnSO_4.7H_2O$, by crystallization from the aq. soln. between —4° and 6°. A. Carnot obtained it in rhombic crystals from the aq. soln. at 6°. C. E. Linebarger said that it can exist over the temp. range of —10° to —5°. The transition temp. between it and the pentahydrate was found by F. G. Cottrell to be 9° ; and between it and the tetrahydrate, 27°—*vide* Fig. 82. R. Brandes observed that the heptahydrate loses 4·9 per cent. of water between 9° and 11° ; and 18·6 per cent. between 12·5° and 15°. It gives up 2 mols. of water to absolute alcohol ; 3 mols. to alcohol of sp. gr. 0·903 ; 4 mols. to boiling absolute alcohol ; 5 mols. to boiling 55 per cent. alcohol ; and none to cold ether. A. Carnot described a native heptahydrate, which he called **mallardite**—after E. Mallard. It was found in a silver mine near Butterfield Canon, Utah. The colourless, monoclinic crystals occur in crystalline masses with a fibrous structure. The heptahydrate thus appears to be dimorphous. E. S. Larsen and M. L. Glenn call the monoclinic minerals with the general formula $RSO_4.7H_2O$, *melanterites*—*e.g.* in a zinc-copper-melanterite the ratio Zn : Cu is between 1 : 1 and 1 : 3 and in copper-zinc-melanterite between 3 : 1 and 1 : 1. E. N. Capon and I. S. Haskes discussed hydrates of the type $[Mn, 8H_2O]^{..}$, and A. Predvoditeleff and W. Blinoff, the hydrates $MnSO_4$ with $\frac{1}{2}$, 1, and $4H_2O$, revealed by their photo-electric effects.

R. Brandes described anhydrous manganous sulphate as a white, friable mass with a bitter, metallic taste ; and O. B. Kühn, the monohydrate as a pale reddish-

yellow powder. H. de Sénarmont, and J. C. G. de Marignac said that the tetra-hydrate forms pale red, monoclinic plates with the axial ratios $a:b:c$ =0·8643 : 1 : 0·5871, and β=90° 53'. W. Schieber said that rhombic prisms are formed between 25° and 30°. A. Carnot, and J. C. G. de Marignac said that the pentahydrate forms triclinic plates, which, according to the latter, have the axial ratios $a:b:c$=0·5449 : 1 : 0·5268, and α=113° 5', β=109° 44', and γ=94° 0'. The (001)-cleavage is incomplete, and, according to E. Mitscherlich, the crystals are isomorphous with pentahydrated cupric sulphate. S. Meyer reported that when crystallized in a magnetic field, the pentahydrate is formed in rhombic plates with the long diagonal parallel to the N : S-poles. If so, the pentahydrate is dimorphous. E. S. Larsen and M. L. Glenn found that the crystals of the penta-hydrate are triclinic, with the optical character negative ; the optical axial angle $2V$ is rather large. The trihydrate is probably monoclinic ; the optical character is negative ; and the optic axial angle $2V$ is moderately large. The monohydrate is probably monoclinic ; the optical character is positive ; and the optical axial angle $2V$ is near 90°—szmikite is probably monoclinic. A. Carnot observed that the heptahydrate forms pale red, monoclinic plates ; and H. V. Regnault added that the form of the crystals resembles that of hydrated ferrous sulphate. For iso-morphous mixtures of the hydrated manganese sulphates with those of hydrated copper, beryllium, magnesium, and zinc, vide infra, in connection with the com-plex salts. J. W. Retgers, and C. F. Rammelsberg discussed isomorphous mixtures with ferrous sulphate (q.v.) ; and E. Dittler, overgrowths with nickel and cobalt sulphates.

H. G. F. Schröder gave 2·954 to 2·975 for the **specific gravity** of anhydrous manganous sulphate ; L. Playfair, 3·386 ; C. H. D. Bödeker, 3·1 at 14° ; C. Pape, 3·192 at 16° ; O. Pettersson, 3·235 to 3·260 at 14·0° to 14·6° ; C. Lepierre, 3·14 at 12° ; and T. E. Thorpe and J. I. Watts, 3·282 at 15°. For the sp. gr. of the monohydrate, O. Pettersson gave 2·870 to 2·905 at 14·2° to 15·4° ; L. Playfair, 3·210 ; and T. E. Thorpe and J. I. Watts gave 2·845 at 15° ; while J. von Schröckinger gave 3·15 for the sp. gr. of szmikite. For the sp. gr. of the dihydrate, T. E. Thorpe and J. I. Watts gave 2·526 at 15° ; and for the trihydrate, 2·356 at 15°. H. Töpsöe gave 2·261 for the sp. gr. of the tetrahydrate ; G. T. Gerlach, 2·107 at 4° ; H. Kopp, 2·092 ; and T. E. Thorpe and J. I. Watts, 2·103 at 15°. For the sp. gr. of the pentahydrate, L. Gmelin gave 1·834 ; H. Kopp, 2·087 to 2·095 ; C. Pape, 2·059 at 16° ; O. Pettersson, 2·099 to 2·107 at 15·2° to 17·6° ; T. E. Thorpe and J. I. Watts, 2·103 at 15° ; and J. L. Andreae, 2·1006 at 14·5°. Observations on the sp. gr. of aq. soln. of manganous sulphate were made by F. Fouqué, O. Schön-rock, W. Manchot and co-workers, F. Flöttmann, C. A. Valson, and P. A. Favre and C. A. Valson. G. T. Gerlach gave for the sp. gr. of soln. at 15°/15° :

$MnSO_4$	5	10	15	20	25	30	35	40	45 per cent.
Sp. gr.	1·0340	1·0690	1·1055	1·1435	1·1835	1·2255	1·2695	1·3135	1·3640

C. M. Pasea :

$MnSO_4$	0·116	0·200	0·288	0·420	0·573	0·708	0·836	1·061 per cent.
Sp. gr.	0·99982	1·00065	1·00151	1·00278	1·00431	1·00566	1·00685	1·0091

F. Flöttmann found the sp. gr. of soln. sat. at 15°, 20°, and 25° to be respectively 1·4772, 1·4866, and 1·4993 ; and J. Wagner gave for N-, 0·5N-, 0·25N-, 0·125N-, and 0·0625N-soln. the respective values 1·0728, 1·0365, 1·0179, 1·0087, and 1·0041 at 25°/4°. B. Cabrera and co-workers found that soln. with C grms. of the anhydrous salt per 1000 grms. of solvent, at θ°, had, for C=384·2, D=1·4547{1—0·00026(θ—20)} ; for C=277·0, D=1·3274{1—0·0032(θ—20)} ; and for C=201·7, D=1·2288{1—0·00030(θ—20)}. J. N. Rakshit calculated for the sp. gr., the **molecular volume,** and the mol. contraction of manganous sulphate, $MnSO_4.nH_2O$:

n . . .	0	1	2	3	4	5	32	42
Sp. gr. . .	3·282	2·845	2·526	2·556	2·261	2·103	1·16917	1·13615
Mol vol. .	45·0	55·7	73·6	86·6	98·2	114·4	—	—
Mol. contr. .	·—	7·3	7·4	12·4	18·8	20·6	0·8	0·07

Observations were made by W. Biltz. E. Moles and M. Crespi discussed the mol. vol. of the water of hydration. A. N. Campbell calculated the modulus for manganese, and the electrostriction as indicated in connection with manganous chloride (q.v.), from the sp. gr. of the aq. soln. :

Eq. per litre .	0·5	0·3	0·2	0·1	0·05	0·02	0·01
Sp gr. 15°/15° .	1·03654	1·02217	1·01493	1·00733	1·00366	1·00142	1·0071
$m_{\frac{1}{2}Mn} \times 10^{-4}$.	365	365	374	364·5	342	345	320
Electrostriction	46·5	48·1	49·6	46·9	46·7	42·3	42·0

I. Traube calculated for the **molecular solution volume,** v :

MnSO₄ .	5	10	15	20	25	30 per cent.
v . .	7·2	9·4	11·8	14·1	16·3	18·4

C. A. Valson found that the **capillary rise** of a normal soln. in a tube of 0·5 mm. diameter at 15° is 57·3 mm. ; L. C. de Coppet, and F. Dreyer also discussed the capillarity of the soln. ; and G. Tammann, the internal pressure. W. H. Whatmough measured the surface tension at 18°; and at 15° the **surface tension,** σ dynes per cm., and **specific cohesion,** a² eq. mm., are :

MnSO₄ .	0	4·77	9·10	13·06	16·68 per cent.
σ . .	73·26	73·86	74·72	75·28	75·82
a² .	14·96	14·38	13·93	13·49	13·10

H. Sentis gave σ=73·71 and 74·62, and a²=15·07 and 14·23 respectively for soln. with 0 and 7·81 per cent. MnSO₄ at 15·5°. J. Wagner gave for the **viscosity,** η (water unity), at 25° :

MnSO₄ .	0	0·0625N-	0·125N-	0·25N-	0·5N-	N-
σ . .	7·557	7·583	7·608	7·658	7·770	7·845
η . .	1·0000	1·0158	1·0366	·1·0761	1·1690	1·3640

W. H. Whatmough represented his results for the surface tension by σ=7·557 +0·163N, where N denotes the normality of the soln. J. C. Graham, and J. C. G. de Marignac measured the rate of **diffusion** of aq. soln. of manganous sulphate.

C. Pape gave 0·182 for the **specific heat** of anhydrous manganous sulphate ; and 0·338 for the pentahydrate ; while H. Kopp gave 0·323 for the pentahydrate between 17° and 46°. J. C. G. de Marignac gave for the sp. ht. of aq. soln. with MnSO₄.nH₂O, 0·9529, 0·9125, and 0·8440 respectively for n=200, 100, and 50, between 19° and 51°. S. Pagliani found the **molecular heat** to be 81+18(n−5). N. de Kolossowsky discussed the subject. R. Brandes observed that the **melting-point** of the heptahydrate is near 19°, and the fusion of the salt is attended by the separation of the dihydrate ; between 9° and 11° the heptahydrate loses about 4 per cent. of water, and 18·6 per cent. between 12·5° and 15°. H. Bolte, and R. Hollmann made observations on this subject—vide infra. W. A. Tilden gave 54° for the m.p. of the pentahydrate. T. Graham observed that if the pentahydrate is dried in air at 115°, the eq. of 3·91 mols. of water are given off, and at ordinary temp., in vacuo, over sulphuric acid, 3·25 mols. J. C. G. de Marignac found that the tetrahydrate slowly effloresces in air ; R. Brandes, that it decrepitates when heated, forming a white powder without melting, and in vacuo, over sulphuric acid, it loses a mol. of water ; and G. J. Mulder, that at ordinary temp. it loses 26·8 per cent. of water in dry air in 45 days ; at 52°, 29·3 per cent. ; at 99°, 29·9 per cent.; at 196°, 31·1 per cent. ; and at 241°, 32·2 per cent. A. Étard found the monohydrate to be stable between 57° and 117°. E. N. Gapon studied some relationships of the m.p. K. Friedrich gave 700° for the m.p. of the anhydrous sulphate; and there is a **transformation point** on the heating curve at 860°. According to J. L. Gay-Lussac, the anhydrous sulphate can be heated to dull redness

without decomposition, but at a higher temp. it can be decomposed to form manganosic oxide. According to K. Friedrich, the decomposition of manganous sulphate commences at 1030°; G. Marchal said that decomposition can be detected at 720°; and that at 1028° the equilibrium press. is atmospheric. C. W. Davis found that at 950° manganese sulphate is completely decomposed to oxides in half an hour. The subject was studied by E. Alberts, and K. Yamamoto and K. Bito.

W. Müller-Erzbach found that 3 mols. of water in the pentahydrate are easily expelled, the fourth mol. passes off at 105°, and the last mol. is retained very tenaciously. R. Hollmann observed the **vapour pressure,** p mm., of the pentahydrate to be $p=13\cdot4$ mm. at 21°. H. Lescoeur found the vap. press. of a sat. soln. to be 11·3 mm. at 20°, and 162 mm. at 60°; while the solid salt at 60° has a vap. press. of 150 to 159 mm. The vap. press. of $MnSO_4.nH_2O$, at 20°, was found to be 11·5, 11·2, and 10·8 mm. for $n=4\cdot55$, 1·9, and 1·15 respectively; 3·9 and 3·0 mm. for $n=1\cdot05$ and 1·00; and at 60°, for $n=1\cdot28$ mm. The salt which had been heated to 160° had no marked vap. press. The results at 20° do not agree with those of H. Bolte, who obtained a continuous curve which corresponded with the following selected values :

	9°	10°	12°	14°	16°	18°	20°
p	5·63	6·18	7·41	8·74	10·10	11·53	12·94

He also obtained the results shown in Fig. 83 at 14·75°; and at 20·01° for the dihydrate because of the smallness of its vap. press. at the lower temp. The vap.
FIG. 83.---Dehydration Curve of Hydrated Manganous Sulphate.

press. of the heptahydrate is 10·5 mm. at 14·75°, and if the hexahydrate exists, its vap. press. must be the same; when the heptahydrate has lost 2 mols. of water, its vap. press. falls to 9·20 mm. at 14·75°; and there is no change as the composition of the hydrate passes from the pentahydrate to the trihydrate. The vap. press. falls to a very small value as the composition approximates to that of the dihydrate—at 20·01° the vap. press. of the dihydrate is 3·48 mm. There is no change with the monohydrate, but the last half mol. of water is retained very tenaciously because its vap. press. is too small for measurement. C. D. Carpenter and E. R. Jette found the vap. press., p mm. of mercury, of the monohydrate to be :

	25°	30·17°	35·17°	40·17°	45·14°	60·29°	65·16°
p	19·8	27·1	37·0	49·1	64·4	138·7	174·7

L. Hackspill and A. P. Kieffer studied the dehydration of the salt by heat; and K. Flick, and H. H. Willard and R. D. Fowler discussed the separation of manganese sulphate from some other sulphates by the fractional dissociation of the sulphates when heated. J. G. F. Druce discussed the creeping of the salt when its aq. soln. is evaporated.

G. Tammann found the **lowering of the vapour pressure** of water by soln. of 0·5, 1, and 2 mols. of manganese sulphate per litre to be respectively 6·0, 10·5, and 21 mm. respectively. The subject was studied by C. Dieterici, and N. Tarugi and G. Bombardini. G. T. Gerlach gave for the **boiling-point** of aq. soln. with 17·1, 32·1, 46·2, 58·9, and 68·4 (sat.) grms. of salt per 100 grms. of water respectively 100·5°, 101°, 101·5°, 102°, and 102·4°. L. Kahlenberg found the **raising of the boiling-point** of water by soln. of 0·246, 0·472, 0·957, and 1·602 mols of salt per 1000 grms. of water to be respectively 0·114°, 0·193°, 0·373°, and 0·678°. The values with over 0·25M-soln. show that at about 100° there is an inclination to form complexes whose effects are greater than those produced by ionization. For the **lowering of the freezing-point** of water L. Kahlenberg gave —0·293°, —0·687°, —1·399°, and —2·591° for soln. with 0·1285, 0·3389, 0·7176, and 1·229 mols per

1000 grms. of water respectively; while H. C. Jones and F. H. Getman obtained for soln. with 0·08, 0·25, 0·41, 0·98, and 1·64 mols of salt per litre the respective values —0·194°, —0·510°, —0·792°, —1·898°, and —3·668°. These results are taken to show that the ionization in dil. soln. is small, and in the case of the 0·08M-soln., it amounts to about 30 per cent. The fact that the calculated mol. depression reaches a minimum with 0·98M-soln. and then increases is supposed to indicate a hydration of the ions or of the molecules in soln. Observations were made by N. Tarugi and G. Bombardini. E. N. Gapon studied the relation between the b.p. and the sp. gr.

For the **heat of formation** J. Thomsen gave $(Mn,O_2,SO_2)=178\cdot79$ Cals.; M. Berthelot gave $(Mn,S,2O_2,Aq.)=263\cdot2$ Cals., and J. Thomsen, 263·7 Cals. J. Thomsen also gave $(Mn,O,H_2SO_4,Aq.)=121\cdot25$ Cals.; $(Mn,H_2SO_{4aq.})=52\cdot9$ Cals. For the **heat of solution** of $MnSO_4$ with $1\cdot050H_2O$, 7·726 Cals.; and $1\cdot960H_2O$, 6·305 Cals.; with $2\cdot998H_2O$, 4·156 Cals.; with $3\cdot912H_2O$, 2·454 Cals.; with $5H_2O$, 0·040 Cals.; and for $MnSO_4$, 13·79 Cals. P. A. Favre and C. A. Valson made observations on the heat of soln. of the pentahydrate. W. P. Jorissen calculated for the **heat of hydration** $MnSO_4+nH_2O$, for $n=1$, 2, 3, 4, and 5 the respective values 5·98, 1·57, 2·09, 1·91, and 2·20 Cals. For the **heat of dilution** of $MnSO_4,20H_2O$ to $MnSO_4,nH_2O$, J. Thomsen gave for $n=50$, 100, and 200 respectively 0·532, 0·714, and 0·792 Cals. The **heat of neutralization** is $\{Mn(OH)_2,H_2SO_4,Aq\}=26\cdot49$ Cals.; and M. Berthelot gave 27·0 Cals. G. Beck discussed the energy of formation.

FIG. 84.—The Heats of Solution of the Hydrated Manganous Sulphates.

R. de Forcrand prepared what he regarded as two series of dihydrates, two series of monohydrates, and two series of anhydrous salts. Starting with the heptahydrate, the *cold series* was made by allowing it to dehydrate by efflorescence, and for the final stages, drying in vacuo over phosphoric oxide. In the *hot series* a cold, sat. soln. of the tetrahydrate was heated to 98°, and evaporated by a current of air playing on the surface of the liquid. The results are tabulated for the heat of soln., Q, of $MnSO_4.nH_2O$ prepared cold, and also hot—J. Thomsen's values are added for comparison:

n		0	0·5	1·0	1·5	2	3	4	5	7
	Cold	19·620	16·300	13·740	—	9·369	5·570	1·853	—0·040	—3·251
Q	Hot	13·570	—	7·635	6·670	5·668	—	—	—	—
	J.T.	13·515	—	7·610	—	6·033	3·962	2·101	—0·089	—

The heats of soln. for the hot series of salts agree with J. Thomsen's values, but for the cold series there is a marked difference from J. Thomsen's values, and the difference increases as the dehydration proceeds (Fig. 84). R. de Forcrand assumed that the anhydrous salt and hydrates of the hot series are polymerides of the corresponding salts prepared in the cold.

E. S. Larsen and M. L. Glenn found the **indices of refraction** for the pentahydrate to be $\alpha=1\cdot495$, $\beta=1\cdot508$, and $\gamma=1\cdot514$; the tetrahydrate, $\alpha=1\cdot509$, $\beta=1\cdot518$, and $\gamma=1\cdot522$; and the monohydrate, $\alpha=1\cdot562$, $\beta=1\cdot595$, and $\gamma=1\cdot632$. The crystals of szmikite have $\alpha=1\cdot57$, and $\beta=1\cdot62$. According to A. N. Campbell, H. C. Jones and F. H. Getman's values for the indices of refraction are affected by a constant error, and he gave:

Eq. per litre	0·5	0·3	0·2	0·1	0·05	0·02	0·01
μ_C . .	1·33770	1·33535	1·33377	1·33253	1·33171	1·33131	1·33123
μ_F . .	1·34378	1·34141	1·33992	1·33866	1·33770	1·33731	1·33723

The calculated values for the solid are $\mu_C=1\cdot54$ and $\mu_F=1\cdot56$. H. C. Jones and F. H. Getman found the indices of refraction, μ, for soln. of 0·08, 0·25, 0·41, 0·98, and 1·64 mols of $MnSO_4$ per litre to be respectively 1·32750, 1·33150, 1·33575,
1·34930, and 1·36357. F. Flöttmann found the index of refraction for the D-line of soln. sat. at 15°, 20°, and 25°, the respective values 1·41120, 1·41235, and 1·41453. N. Embirikos, and P. Krishnamurti studied the Raman effect. A. Predvoditeleff and W. Blinoff found the **photoelectric activities** of the hydrates $4MnSO_4.H_2O$, and $2MnSO_4.H_2O$ to be respectively 4·25 and 1·8 times larger than the photo-electric activity of the anhydrous salt. R. Robl observed no fluorescence in ultra-violet light. H. Jahn, G. Quincke, R. Wachsmuth, and O. Schönrock made observations on the **electromagnetic rotation** in aq. soln., and found for a normal soln., 1·14, with water unity ; R. Wachsmuth found that for a soln. with 17·136 grms. of $MnSO_4$ in 100 c.c. of soln., the electromagnetic rotation is 1·02904 (water unity), the sp. rotation 0·2317, and the mol. rotation 1·9433 ; and O. Schönrock, that for soln. with 30·819 to 41·996 grms. of $MnSO_4$ per 100 c.c. of soln., the sp. rotation is 0·3075, and the mol. rotation 2·579. L. R. Ingersoll gave for Verdet's constant for light of wave-lengths 0·6, 0·8, 1·0, and 1·25μ respectively 0·0178, 0·0101, 0·0066, and 0·0043 for soln. of manganous sulphate of sp. gr. 1·369. F. Allison and E. J. Murphy studied the magneto-optic properties ; A. E. Lindh, D. Coster, and O. Stelling, the X-ray spectrum ; and B. K. Mukerji and N. R. Dhar, the photosensitization of aq. soln.

E. Klein measured the **electrical conductivity**, λ, of aq. soln. with an eq. of the salt in v litres at 18°, and found :

v	0·689	1·476	2·034	3·231	4·257	5·213	6·639
λ	27·6	21·34	18·29	13·40	9·98	7·20	4·52

Observations were also made by H. C. Jones and F. H. Getman ; while L. G. Winston and H. C. Jones obtained for the conductivity, μ, of soln. with a mol of the salt in v litres from 0° to 35°, to which are added results by H. H. Horsford and H. C. Jones for temp. from 50° to 65° :

v		4	8	32	128	512	1024	2048	4096
	0°	37·25	44·11	59·65	79·46	97·99	107·12	116·15	124·47
	25°	67·17	79·77	109·27	147·24	184·58	202·94	221·33	238·20
μ	35°	79·11	94·06	129·72	176·10	222·69	245·72	268·33	289·39
	50°	88·0	112·8	156·4	204·1	277·5	—	326·7	—
	65°	108·3	130·0	181·8	241·9	338·7	—	404·6	—
	0°	29·9	35·4	47·9	63·8	78·7	86·1	93·3	100·0
a	25°	28·2	33·5	45·9	61·8	77·5	85·2	92·9	100·0
	35°	27·3	32·5	44·8	60·8	76·9	84·9	92·7	100·0

The results for low concentrations above 35° indicate that **hydrolysis** probably occurs. R. Brandes said that the aq. soln. reddens blue litmus very faintly. W. N. Hartley showed that the absorption spectrum of dil. soln. agrees with the assumption that hydrolysis and oxidation produce colloidal $MnO(OH)_2$. M. Chanoz calculated that a 0·5N-soln. is hydrolyzed to the extent of 0·02 per cent. The percentage **degrees of ionization,** a, calculated by L. G. Winston and H. C. Jones, are indicated above. N. Tarugi and G. Bombardini studied this subject. W. Manchot and co-workers estimated the solvation of the salt in aq. soln. and found that a mol. of the salt is loaded respectively with 22·6 and 17·6 mols. of water in soln. containing 14·797, and 29·594 grms. in 100 c.c. of soln. J. B. O'Sullivan measured the H·-ion conc. of aq. soln. H. Rieckhoff and H. Zahn discussed the high-frequency conductivity of aq. soln. ; and T. Dahlblom, the relation between the conductivity and the vap. press. of the soln. O. F. Tower observed that the **electrode potential** of a manganese dioxide electrode in soln. of manganous sulphate of conc. C_{Mn}, with sulphuric acid having a H·-ion conc. of C_H, can be represented by $\pi = -0·0286 \log (C_{Mn}C_H{}^4/C_{Mn'}C_H{}'^4)$, where $C_{Mn'}$ and $C_{H'}$ refer to concentrations in another soln. K. F. Ochs measured the potential of platinum and a soln. of manganous sulphate and sulphurous acid. W. Haehnel found that the curve for **decomposition voltage** of soln. of manganous sulphate has three singular points as illustrated in Fig. 86 for soln. with [H·]=0·1588, and [Mn··]=0·1325. M. Ber-

thelot observed that in the **electrolysis** of dil. soln. of the salt hydrogen appears at the cathode and manganese dioxide at the anode; but with intense currents oxygen appears at the anode and manganese at the cathode. K. Elbs, and E. Frei observed that with a low acid conc., manganese dioxide is formed; with a larger acid conc., the soln. acquires a red colour; and with a still larger acid conc., manganese dioxide is no longer deposited, and all the manganese remains in soln., forming a dark red liquid. The amounts of sulphuric acid—in grms. per 100 c.c.—which prevent the separation of manganese dioxide for soln. containing M mols of $MnSO_4$ per litre, are as follow:

m	0·01	0·02	0·10	0·15	0·20	0·50	1·00
H_2SO_4 $\{$ 16°	3·5	16·5	40·0	40·5	39·5	34·0	29·0
60°	27·0	37·0	59·0	59·0	58·5	54·0	45·0
80°	44·0	54·0	70·5	58·3	68·5	58·0	—

A low temp. is favourable for the formation of permanganate; and a high acid conc. favours the formation of manganic sulphate. With lead anodes manganic acid is formed only with very dil. soln. of manganous sulphate, and with conc. soln. a brown precipitate of manganic sulphate is formed. With strongly acidic soln. of manganous sulphate some sulphate of quadrivalent manganese is formed—
Fig. 85.—Potentials of Solutions of Manganous and Manganic Sulphates.
Fig. 86.—Decomposition Voltage of Solutions of Manganous Sulphate.

vide supra, permanganate. W. J. Müller observed no oxidation when zinc anodes are used, but with passive iron manganese dioxide is formed with a current density of 0·01 amp. per sq. cm. The electrolytic oxidation of manganous sulphate was studied by F. Weckbach. A. Schumrick measured the potential, E_H, of $MnSO_4$-$Mn_2(SO_4)_3$ and $Mn_2(SO_4)_3$-$Mn(SO_4)_2$ soln. using smooth platinum electrodes and MnO_2 electrodes, since platinized platinum electrodes decompose the sulphates of ter- and quadrivalent manganese. A selection from the results is illustrated by Fig. 85 with soln. in $8M$-H_2SO_4. J. Beck also studied the electrolytic oxidation of soln. of manganous sulphate. G. Grube and K. Huberich found the oxidation potentials of a soln. of 0·05 gram-atom of manganese in a litre of $15N$-H_2SO_4 at 12° are $Mn^{\cdot\cdot} \rightarrow Mn^{\cdot\cdot\cdot} = 1\cdot511$ volts; $Mn^{\cdot\cdot\cdot} \rightarrow Mn^{\cdot\cdot\cdot\cdot} = 1\cdot62$ volts; and $Mn^{\cdot\cdot} \rightarrow Mn^{\cdot\cdot\cdot\cdot} = 1\cdot577$ volts. The potentials are dependent on the conc. of the acid, and to a far less extent on the conc. of the manganese. Increasing the conc. of the acids displaces the potentials to less positive values. The equilibrium constant for the reaction $Mn_2(SO_4)_3 \rightleftharpoons MnSO_4 + Mn(SO_4)_2$ is $K = C_{Mn}^{\cdot\cdot} C_{Mn}^{\cdot\cdot\cdot\cdot}/C^2_{Mn}^{\cdot\cdot\cdot}$, and $K = 0\cdot005032$. The value of the constant changes with the acidity and the conc. of the manganese, and with $0\cdot05M$-$Mn_2(SO_4)_3$ in $9\cdot1N$-H_2SO_4, about 36 per cent. is decomposed in accord with the equation, but with a $24\cdot2N$-H_2SO_4, only $6\cdot7$ per cent., so that the reaction is displaced to the left of the equation with

increasing acidity.   If K denotes the equilibrium constant, and α the percentage decomposition of manganic sulphate :

$N\text{-}H_2SO_4$	24·2	19·8	16·7	15·0	12·1	10·6	9·1
K	0·0013	0·0040	0·0050 ●	0·0052	0·0127	0·0283	0·0698
α	6·7	11·0	12·0	13·0	18·0	25·0	36·0 per cent.

This equilibrium condition explains the abnormal behaviour of manganic sulphate on hydrolysis, for the products are manganous sulphate and hydrated oxide of quadrivalent manganese.   One product of the hydrolysis is the disulphate, $Mn(SO_4)_2$, and this is the most easily hydrolyzed component of the mixture, equilibrium is disturbed, still more manganic sulphate is hydrolyzed, so that the reaction takes place completely from left to right.   T. Swensson observed a small increase in the e.m.f. of a cell of a soln. of the salt when one electrode is exposed to light ; the subject was studied by J. Lifschitz and S. B. Hooghoudt.

P. Théodoridès found the **magnetic susceptibility** of solid manganese sulphate to be $88·72 \times 10^{-6}$ mass unit, and C. Chéneveau gave 85×10^{-6} mass unit; for $2N\text{-}MnSO_4$, G. Quincke gave $29·1 \times 10^{-6}$ mass unit; G. Jäger and S. Meyer gave for 14·83, 20·97, and 37·74 per cent. soln. the respective values 18×10^{-6}, $28·4 \times 10^{-6}$, and $56·2 \times 10^{-6}$ mass unit ; P. Pascal, 1500×10^{-5}; G. Falckenberg gave 93×10^{-6} mass unit for an aq. soln.; and O. Liebknecht and A. P. Wills, 100×10^{-6} mass unit.   Observations were also made by G. Piaggesi, P. Plessner, G. Falckenberg, R. H. Weber, L. C. Jackson and H. K. Onnes, P. Théodoridès, W. Albrecht, O. Wylach, P. Philipp, B. Cabrera and co-workers, and A. Heydweiller.   W. Sucksmith studied the gyromagnetic effect.   B. Cabrera and co-workers found for aq. soln. of 0·3633 and 0·01808 grm. of the anhydrous salt per 1000 grms. of solvent, mol. susceptibilities respectively 0·014981 and 0·14803, so that $4·354 = \chi(T + \Theta)$. K. Honda and T. Sone gave for the magnetic susceptibility, $\chi \times 10^6$ mass units :

	$-178°$	$-140°$	$-70°$	$0°$	$250°$	$507°$	$747°$	$1148°$
$\chi \times 10^6$	261	183	124	94·1	55·6	38·6	30·0	14·0

H. Mosler found the temp. coeff., a, of the magnetization of 13, 23, 30·1, and 40·2 per cent. of manganous sulphate to be respectively 0·00288, 0·00261, 0·00259, and 0·00255.   J. Aharoni and F. Simon observed that the susceptibility of a soln. of 106·64 grms. of $MnSO_4$ per litre expressed in arbitrary units is -1550, the susceptibility per gram for different dilutions is nearly 6·87, and when soln. and water are mixed in the following proportions by volume :

Soln. : H_2O	1 : 0	12 : 3	12 : 15	10 : 17	7·98 : 19	6·02 : 21	4 : 23
Susceptibility	-155	-120	$-54·4$	$-38·8$	$-25·0$	$-12·4$	$-1·6$

J. A. Arfvedson found that **hydrogen** reduces red-hot manganous sulphate to form an oxysulphide.   According to W. Ipatieff and W. Kisseleff, when an aq. soln. of manganous sulphate is treated with hydrogen, at 300° and over 150 atm. press., manganese sulphide is formed.   J. A. Arfvedson found that when heated to a high temp. in **air**, this sulphate is decomposed as indicated above.   R. Brandes said that the anhydrous salt absorbs **water** with great avidity from air, forming a hard mass ; and when exposed to air it forms the trihydrate.   The solubility of the salt in water has been previously discussed.   J. H. Weibel studied the hydrolysis of the salt, and observed no separation at 150°, but at 250° a precipitate is formed. M. O. Charmandarian and E. A. Alexeeva found that manganese sulphate has a feeble catalytic effect on the decomposition of **hydrogen dioxide.**   A. Gorgeu observed that when a 20 to 25 per cent. soln. of manganous sulphate is boiled with a 2 to 3 per cent. soln. of **sodium hydroxide,** the white precipitate first formed is converted into a pink crystalline precipitate, which is not decomposed by continued washing with water, remains unaltered when exposed to air, and does not lose weight at 200°.   Its composition corresponds with **manganese oxydisulphate,** $MnO.2MnSO_4.3H_2O$.   R. Fink found that if $0·1N\text{-}MnSO_4$ be digested with **magnesium hydroxide** on a water-bath, 71·2 per cent. of the manganous oxide is pre-

cipitated. F. Fichter and E. Brunner observed that manganous sulphate in the presence of sulphuric acid is more readily oxidized by fluorine than is the case with manganous fluoride, presumably owing to the intervention of sulphur tetroxide in the oxidizing process. The formation of manganic sulphate, the first step, is easy to recognize, by the red colour. On continued passage of fluorine this colour changes to a brownish-red and finally to a dark brown, and the oxidizing power corresponds to a nearly complete transformation into the labile sulphate of quadrivalent manganese, $Mn(SO_4)_2$. If the concentration of the sulphuric acid is not high, hydrolysis sets in and manganese dioxide is formed; but although it is easy to obtain a yield exceeding 90 per cent., the formation of manganese dioxide is not a certain proof of the primary formation of a salt of quadrivalent manganese, for it may be formed by hydrolysis of manganic sulphate, one-half of which is reduced to manganous sulphate and subsequently re-oxidized. In order to bring the oxidation to the highest stage, permanganic acid, it is useful to have a low concentration of manganous ions and a high concentration of sulphuric acid, the latter being necessary to avoid the formation of hydrogen dioxide. In these circumstances the characteristic colour of permanganate ions becomes visible the more quickly the smaller the concentration of manganous sulphate. A. B. Prescott found that very little sulphuric acid is displaced when the salt is evaporated with **hydrochloric acid.** F. Ephraim observed no addition compound with hydrogen chloride. A. B. Prescott observed that when a gram of the salt is treated with 4·035 grms. of hydrochloric acid of sp. gr. 1·153 and evaporated to dryness, 0·8 per cent. of the salt is converted to chloride.

H. Rose found that when the anhydrous sulphate is heated with **sulphur** in a current of hydrogen, or, according to A. Violi, with sulphur alone, manganous sulphide is formed: $MnSO_4 + 2S = MnS + 2SO_2$; while G. Vortmann and C. Padberg observed that the aq. soln. is not changed by sulphur. L. Meyer observed it to be a good catalyst in the oxidation of **sulphur dioxide.** J. T. Norton found that when the soln. is heated with **sodium thiosulphate** in a sealed tube at 140° to 200°, some manganous sulphide is formed. According to C. Schultz, when a soln. of manganese sulphate in boiling, conc. **sulphuric acid** is cooled, anhydrous, asbestos-like, prismatic crystals are formed, and at 100° crystal plates of **manganous hexahydrotetrasulphate,** $Mn(HSO_4)_2.2H_2SO_4$, are produced; and if sulphuric acid of sp. gr. 1·6 is employed, tabular crystals of

FIG. 87.—The Ternary System: $MnSO_4$–H_2SO_4–H_2O.

manganous hydrosulphate, $Mn(HSO_4)_2$, separate from the cooling soln. A. Schumrick found that a litre of 7M-, 8M-, 10M-, and 12M-H_2SO_4 dissolves respectively 7·22, 4·00, 2·50, and 2·10 grms. of manganous sulphate. C. Montemartini and L. Losana studied the system $MnSO_4$–H_2SO_4–H_2O, and the results at 12·5°, summarized in Fig. 87, are a little uncertain as to the exact regions of the different phases. There are **manganese hydrodisulphate,** $MnSO_4.H_2SO_4$; the *monohydrate,* $MnSO_4.H_2SO_4.H_2O$; and **manganese hydrotetrasulphate,** $MnSO_4.3H_2SO_4$.

W. R. E. Hodgkinson and C. C. Trench found that when manganous sulphate is heated in a current of **ammonia** gas, the residue is an equimolar mixture of manganous sulphide and oxide, but no nitride is formed. G. Gore said that the anhydrous sulphate is insoluble in liquid ammonia. H. Rose found that the anhydrous sulphate absorbs dried ammonia gas very slowly to form a white powder of **manganous tetramminosulphate,** $MnSO_4.4NH_3$, which can be preserved in a sealed tube; but it loses ammonia in air, and when dissolved in water deposits

manganous hydroxide.   M. A. Rukazin studied the tetrammine.   W. Peters, and
F. Ephraim said that under the conditions indicated by H. Rose **manganous
hexamminosulphate**, $MnSO_4.6NH_3$, can be formed; and when this is kept in
vacuo, it passes into **manganous diamminosulphate**, $MnSO_4.2NH_3$.   The mono-
hydrated sulphate forms **manganous aquopentamminosulphate**, $MnSO_4.5NH_3.H_2O$.
F. Müller gave $-18°$ to $74°$ for the dissociation temp. of the hexammine; $74°$
for the pentammine; $180°$ for the diammine; and over $380°$ for the monammine.
W. Herz studied the equilibrium between soln. of manganous sulphate and
ammonium salts—*vide supra*, manganous hydroxide.   W. Feldt observed that
hydroxylamine forms **manganous hydroxylaminosulphate**, $MnSO_4.NH_2OH.2H_2O$,
as an insoluble white powder; and N. Pfanner obtained $4MnSO_4.3NH_2OH.2H_2O$,
by the action of manganese on an aq. soln. of hydroxylamine sulphate.   H. Franzen
and O. von Mayer found that with hydrazine and manganous sulphate there is
formed **manganous dihydrazinosulphate**, $MnSO_4.2N_2H_4$.   W. Manchot and
co-workers found that at $25°$ soln. with 0, 14·194, and 29·143 grms. $MnSO_4$ per
100 c.c. dissolve respectively 53·3, 30·6, and 17·0 c.c. of **nitrous oxide** per 100 c.c.

E. Kunhein observed a reduction to sulphide when the sulphate is heated in
the arc with **carbon.**   According to J. L. Gay Lussac, when a mixture of manganous
sulphate and carbon is heated to redness, there are formed sulphur dioxide and
carbon monoxide and dioxide, as well as a mixture of manganous oxide and sulphide;
and when the sulphate is heated in a current of **carbon monoxide,** manganous
oxide and sulphide are formed.   W. Manchot and co-workers found that at $25°$
soln. with 0, 14·797, and 29·594 grms. per 100 c.c. dissolve respectively 95·7, 54·8,
and 31·4 c.c. of **acetylene.**   R. Brandes observed that anhydrous manganous
sulphate is insoluble in absolute **alcohol;** and 100 parts of 50 per cent. alcohol
dissolve 2 parts of the salt; and 100 parts of alcohol of sp. gr. 0·872 dissolve 0·63
part of salt.   With the heptahydrate and boiling absolute alcohol the trihydrate
is formed; and a similar product is obtained by the action of absolute alcohol on
the tetrahydrate.   G. C. Gibson and co-workers found the solubility of manganese
sulphate—S grm. of salt per gram of alcohol—in anhydrous alcohols to be:

		15°	25°	35°	45°	55°
S {	Methyl .	0·00190	0·00114	0·00064	0·00043	0·00029
	Ethyl .	0·00012	—	0·00014	—	0·00021

The methyl alcohol had the sp. gr. 0·78656 at $25°/4°$, and the ethyl alcohol, 0·78510.
H. Schiff found that 100 parts of a sat. soln. in 0, 10, 50, and 60 per cent. alcohol

contain respectively 56·25,
51·4, 2·0, and 0·66 parts of
pentahydrated manganous
sulphate.   When the hepta-
hydrate is dissolved in 15 to
50 per cent. alcohol, the
liquid separates into two
layers; the lower layer con-
tains less (12 to 14 per cent.)
alcohol and more (47 to 49
per cent.) salt, and the
upper layer contains more
(50 to 55 per cent.) alcohol
and less (1·3 to 2·2 per cent.)
FIG. 88.—The Ternary System: $MnSO_4$–H_2O–C_2H_5OH.   salt.   With 15 to 50 per

cent. alcohol the separation takes place at ordinary temp., but with 13 to 14 per
cent. or 60 per cent. or upwards of alcohol warming is necessary for the separa-
tion.   F. A. H. Schreinemakers and J. J. B. Deuss studied the ternary system
$MnSO_4$–H_2O–C_2H_5OH at $0°$, $25°$, $30°$, $35°$, and $50°$.   The diagram, Fig. 88, is
characterized by a binoidal surface $kuvk'v'u'$ representing the conditions for the

co-existence of two liquid layers. This region extends from 5·3° to 43·5°. Usually the ternary system of salt, water, and alcohol exhibits only a minimum critical mixing temp., but in the present case there are both a minimum and a maximum critical temp. *abuku'e* represents the surface of the heptahydrate; *bcvu*, the saturation surface of the pentahydrate in contact with the liquid layer poor in alcohol, and *u'v'fe*, the pentahydrate in contact with the liquid layer rich in alcohol; which *cdmgfv'k'v* refers to the monohydrate, and *gmlh* to anhydrous manganous sulphate. The curves *eu* and *ub* refer to soln. sat. with both the hepta- and penta-hydrates; *fv'* and *eu'*, to soln. sat. with both the penta- and monohydrates; and *gm*, to soln. sat. with the monohydrated and anhydrous salts. The curve *kuvk'v'u'* is derived from the following data, where concentrations are expressed in percentages :

		10°	15°	21°	25°	30°	35°	41°	43°
Alcohol poor layer	C_2H_5OH	13·78	9·25	6·10	6·81	8·69	9·24	11·93	14·33
	$MnSO_4$	25·25	29·79	35·05	33·72	30·15	28·61	24·97	22·01
Alcohol rich layer	C_2H_5OH	37·06	44·56	53·55	53·09	45·30	41·71	34·01	31·42
	$MnSO_4$	5·44	2·79	1·10	1·23	2·40	3·44	5·86	8·51

$$\underbrace{\hspace{5cm}}_{MnSO_4.5H_2O} \qquad \underbrace{\hspace{4cm}}_{MnSO_4.H_2O}$$

The percentage solubilities of the hydrates of manganous sulphate in mixtures of alcohol and water are shown in Table III. E. Cuno said that the effect of temp.

on the composition of the two layers is small ; and that if A, W, and S respectively denote the quantities of alcohol, water, and salt in 100 c.c. of soln., the expressions suggested by G. Bodländer, namely $WS^{-\frac{1}{2}}$, and by W. Herz and M. Knoch, namely $(S+A)W/(S+A+W)$, are fairly constant for medium concentrations of alcohol. For a given quantity of salt in the soln., the electrical conductivity rapidly diminishes as the quantity of alcohol increases ; and an increase in the proportion of alcohol leads to a displacement of the maximum conductivity in the direction of soln. containing less salt. E. Darmois studied the effect of manganous sulphate on the rotatory power of tartrates. W. Eidmann, and A. Naumann found that

manganous sulphate is insoluble in **acetone**; A. W. Davidson found the sulphate to be insoluble in acetic acid; A. Naumann, that it is insoluble in **ethyl acetate**, and in **benzonitrile**; F. W. O. de Coninck, that 100 grms. of a sat. soln. in **glycol** contain 0·5 grm. manganous sulphate; R. Brandes, that the salt is insoluble in absolute **ether**, and that no water of crystallization is removed by the ether; and R. Brandes, that the salt is insoluble in boiling **turpentine**, but a mol. of water is removed from the tetrahydrate. S. Hakomori studied the action of **oxalic acid**. F. Krauss and E. Bruchhaus studied the action of the sulphate on **potassium oxalate** in light. H. Grossmann and B. Schück obtained a complex **manganous ethylenediaminosulphate**, $MnSO_4.C_2H_4(NH_2)_2.H_2O$, in triclinic prisms of sp. gr. 1·941; and H. Schjerning, **manganous diphenylhydrazinosulphate**, $MnSO_4.2C_6H_5NHNH_2.H_2O$, soluble in 55 parts of water at 16°. O. C. Magistad observed that the manganese of manganous sulphate will replace the calcium of zeolites.

According to V. Macri, with a few exceptions the **metal hydroxides** are not oxidized by manganous salts. H. Busch studied the adsorption of manganous salts by hydrogels of **ferric hydroxide**. When an ammoniacal soln. of **copper sulphate** and manganous sulphate is boiled, cuprous oxide is precipitated, and the super-natant, colourless liquor gradually becomes blue when exposed to air. Manganous sulphate completely precipitates silver from a hot, ammoniacal soln. of **silver nitrate**. The white precipitate formed by adding a manganous salt to an ammoniacal soln. of **mercuric nitrate** turns grey and then brown on boiling, and after treatment with sulphurous acid, or an acidified soln. of a sulphite, it leaves a heavy, brownish-grey, pulverulent deposit, which is not dissolved by dil. nitric acid, but is readily attacked by the conc. acid, forming nitrous fumes. The addition of ammonia to a soln. containing a **cobalt salt** and manganous salt yields a pre-cipitate of manganous hydroxide which gradually becomes brown, not, however, by the direct reduction of the cobalt oxide, since the latter first undergoes per-oxidation in air, and then gives up its oxygen to the manganese, especially on shaking the mixture.

J. F. John prepared **ammonium manganous disulphate**, $(NH_4)_2SO_4.MnSO_4.6H_2O$, by crystallization from a soln. of the component salts; and C. Lepierre, by crystal-
FIG. 89.—Ternary System :
$MnSO_4$–$(NH_4)_2SO_4$–H_2O at 25°.
FIG. 90.—Ternary System :
$MnSO_4$–$(NH_4)_2SO_4$–H_2O at 50°.

lizing an aq. soln. of ammonium manganous trisulphate. O. Aschan obtained the salt by the action of a soln. of ammonium persulphate on manganese. H. A. von Vogel observed that the hexahydrate first crystallizes from a soln. of ammonium chloride and manganous sulphate—a complex chloride remains in soln. F. A. H. Schreinemakers studied the ternary system $MnSO_4$–$(NH_4)_2SO_4$–H_2O at 25° and 50°, and the results are summarized in Figs. 89 and 90. The region of stability for $(NH_4)_2SO_4.MnSO_4.6H_2O$ is shown by the shaded area over gb, Fig. 89,

so that *gf* represents the solubility curve of pentahydrated manganous sulphate ; *fb*, the solubility curve of the complex salt just indicated ; and *ba*, the solubility curve of ammonium sulphate. R. M. Caven and W. Johnston investigated the same system at 0°, and obtained results analogous to those at 25° obtained by F. A. H. Schreinemakers. It was also observed that the increase in solubility of manganous sulphate caused by ammonium sulphate at 25°, and the decrease in solubility of ammonium sulphate caused by manganous sulphate at 25°, are accentuated at 0°. E. Rouyer observed evidence of the formation of this salt in soln. at 100°. For preparing ammonium manganous disulphate the aq. soln. of the mixed salts should be evaporated between 0° and 25° ;

Fig. 91.—Equilibrium Conditions of Ammonium and Manganous Sulphates.

the salt was also studied by M. T. Salazar and E. Molès. The results of A. Benrath are summarized in Fig. 91.

According to E. Mitscherlich, the pale pink monoclinic crystals of the salt resemble those of the magnesium salt. A. Murmann and L. Rotter gave for the axial ratios $a : b : c = 0.736 : 1 : 0.497$, and $\beta = 107° 2'$. H. G. F. Schröder found the sp. gr. to be 1·825 ; R. Krickmeyer gave 1·837 at 18°/4°. H. A. von Vogel observed that the salt loses some water of crystallization between 75° and 87°, and at a red-heat all the ammonium sulphate is expelled. N. Schiloff and B. Nekrassoff studied the adsorption of the soln. by schönite. F. Ephraim and P. Wagner found the mol. vol. to be 214·9 ; and the dissociation press. to be 400 mm. at 87°. According to T. Graham, the heat of soln. is −9·7 Cals. T. Swensson observed a small increase in e.m.f. when an electrode in a soln. of the salt is illuminated. O. Liebknecht and A. P. Wills gave 53×10^{-6} mass unit for the magnetic susceptibility of the aq. soln. L. C. Jackson and W. J. de Haas, K. S. Krishnan, and L. C. Jackson and H. K. Onnes also examined the paramagnetism at low temp. C. Borel gave 5·91 for the dielectric constant for $\lambda = \infty$. J. F. John found that the salt deliquesces in moist air and is freely soluble in water ; according to J. Locke, 100 parts of water at 25° dissolve 35·1 grms. or 0·1321 mol of the salt. In the absence of air aq. ammonia gives no precipitate with soln. of this salt.

According to C. Lepierre, if a mixture of approximately equal parts of ammonium and manganous sulphates be fused, all the water of crystallization is expelled at 200°, and at 250° crystals of **ammonium manganous trisulphate**, $(NH_4)_2SO_4.2MnSO_4$, are formed. The excess of ammonium hydrosulphate is washed out by boiling in 70 per cent. alcohol. The conditions of formation in aq. soln. at 50° were found by F. A. H. Schreinemakers and are represented in Fig. 90. From this it follows that ammonium manganous disulphate dissociates at 50° : $(NH_4)_2Mn(SO_4)_2.6H_2O = (NH_4)_2SO_4.MnSO_4 + Solution$; and a soln. of eq. proportions of the component salts at 50° furnishes crystals of ammonium manganous trisulphate. W. Lang prepared this salt in anhydrous crystals by adding excess of ammonium sulphate to a hot acid soln. of manganous sulphate; it is decomposed by cold water into the double sulphate, $MnSO_4.(NH_4)_2SO_4$, and manganous sulphate. C. Lepierre found that the white tetrahedral crystals belong to the cubic system, and have a sp. gr. 2·56 at 14°. The aq. soln. of this salt deposits crystals of the complex disulphate when evaporated at low temp. When heated to redness the ammonium sulphate is driven off. M. T. Salazar and E. Molès observed no hydrolysis in the aq. soln. of ammonium manganous sulphate. According to A. Gorgeu, when an aq. soln. of the mixed sulphates is treated with ammonia, added drop by drop at 80°, crystals of **ammonium manganous oxytrisulphate**, $(NH_4)_2SO_4.MnO.2MnSO_4.3H_2O$, are formed. The pale pink rhombic prisms are not changed by dry air, but at 180° water is given off, and at a dull red-heat manganous sulphate remains. The salt dissolves in water, and the soln. deposits

manganous hydroxide.   The salt is soluble in hydrochloric acid without coloration
or the evolution of chlorine.   T. Curtius and F. Schrader evaporated a mixed
soln. of manganous and hydrazine sulphates, and obtained **hydrazine manganous
disulphate**, $(N_2H_5)_2SO_4.MnSO_4$, as a white crystalline powder with a reddish
tinge.   100 parts of water at 18° dissolve 1·67 parts of the salt.   The reactions of
the aq. soln. resemble those of the component salts.   G. Canneri prepared **guani-
dine manganous disulphate**, $(CH_5N_3)_2H_2SO_4.MnSO_4.6H_2O$.

G. Calcagni and D. Marotta measured the f.p. of binary mixtures, **lithium and
manganous sulphates.**   The results show a simple eutectic, Fig. 92.   The region
a refers to a homogeneous liquid ; *b*, to a liquid with solid lithium sulphate ; *c,.*
to a liquid with solid manganous sulphate ; and *d*, to solid β-$MnSO_4$ and β-Li_2SO_4.
The corresponding curve for sodium and manganous sulphates, Fig. 93, shows the
existence of two compounds—**hexasodium manganous tetrasulphate**, $3Na_2SO_4$.
$MnSO_4$, which is unstable above 420°; and **sodium trimanganous tetrasulphate**,
$Na_2SO_4.3MnSO_4$, melting at 715°.   The area *b*, Fig. 93, refers to liquid and solid
soln. *b* ; *c*, to liquid and solid sodium manganous tetrasulphate ; *d*, to liquid and
solid soln. *d* ; *e*, to solid soln. *b* and the compound $3MnSO_4.Na_2SO_4$; *f*, to solid
soln. *b* and compound $MnSO_4.3Na_2SO_4$; *g*, to compounds $3MnSO_4.Na_2SO_4$ and
$MnSO_4.3Na_2SO_4$; *h*, to solid soln. *b* and β-Na_2SO_4 ; and *i*, to the β-modifications
of the two components.   P. L. Geiger found that when the mixture of sodium
chloride, manganese dioxide, and sulphuric acid employed in making chlorine is dried
FIG. 92.—Freezing-Point Curves of
the System : Li_2SO_4–$MnSO_4$.
FIG. 93.—Freezing-Point Curves of
the System : Na_2SO_4–$MnSO_4$.

and heated to redness, the product extracted with water, and the soln. evaporated,
crystals of sodium sulphate separate out.   When the mother-liquor is allowed to
stand in a cool place, **sodium manganous sulphate** separates out in deliquescent
crystals of the *tetrahydrate*, $Na_2SO_4.MnSO_4.4H_2O$; and the mother-liquor deposits
after a long time deliquescent crystals of the *dihydrate*, $Na_2SO_4.MnSO_4.2H_2O$.
O. Aschan obtained the salt by the action of sodium persulphate on manganese.
M. Berthelot gave for the heat of formation $(Na_2SO_4,MnSO_4)=1·2$ Cals.; and
T. Graham, and M. Berthelot, $(MnSO_4,Na_2SO_4,Aq.)=12·0$ Cals. ; and for the heat
of soln. of the dihydrate, 3·2 Cals.; while J. Thomsen gave 13 Cals. for the heat
of soln. of $Na_2Mn(SO_4)_2$.   A. R. Arrott observed that the dihydrate is formed if
a soln. of the constituent salts is cooled above 36·5°—say 40° to 50°.   J. C. G. de
Marignac could not determine the form of the crystals with certainty.   If the
soln. of the component salts be evaporated spontaneously at ordinary temp.,
J. C. G. de Marignac, A. Scacchi, and C. F. Rammelsberg obtained pale pink mono-
clinic crystals of the tetrahydrate with axial ratios $a : b : c=1·344 : 1 : 1·336$, and
$\beta=99°$ 18'.   P. L. Geiger thought that the salt is the pentahydrate ; and L. Gmelin,
the hexahydrate mixed with some dihydrate.   P. L. Geiger said that this salt has
at first a cooling, bitter taste, which afterwards appears unpleasant and metallic.
The salt reddens litmus slightly.   It effloresces in warm air; it decrepitates
slightly when heated, and swells up to a white porous mass ; at a low red-heat
it fuses to a light grey mass which is soluble in water ; some manganosic oxide
may be left when the mass dissolves in water if the calcination temp. has been

high enough. 100 parts of boiling water dissolve 98 parts of salt, and nothing separates out as the soln. cools; but if, after 24 hrs., the soln. is seeded with a crystal of the salt, there is deposited in about 3 hrs. a thick mass of sodium sulphate crystals; and the mother-liquor holds manganous sulphate in soln. F. A. H. Schreinemakers and D. J. van Prooije investigated the ternary system $MnSO_4$–Na_2SO_4–H_2O at 35°. The isotherm ab, Fig. 94, shows the composition of a soln. sat. with Na_2SO_4; bc, of a soln. sat. with hexasodium manganous tetrasulphate, $MnSO_4.3Na_2SO_4$; cd, of a soln. sat. with **sodium manganous enneadecasulphate,** $9MnSO_4.10Na_2SO_4$; and dc, of a soln. sat. with hydrated manganese sulphate, $MnSO_4.H_2O$. There was no evidence of the formation of the double salts $MnSO_4.Na_2SO_4.2H_2O$ and $MnSO_4.Na_2SO_4.4H_2O$, described by J. C. G. de Marignac, and A. Geiger. There is nothing to show whether the latter are metastable salts or mixtures when formed under conditions where Fig. 94 is applicable. The results of R. M. Caven and W. Johnston are illustrated in Fig. 95. The dotted curves refer to a temp. of 35°, the others to one of 25°. No double salt is formed at 0°; the salt $MnSO_4.Na_2SO_4.2H_2O$ is stable at 25° and 35°. The two salts were described by F. A. H. Schreinemakers and D. J. van Prooije. The near coincidence of the double salt portions at 25° and 35° shows that the solubilities of the two salts are
FIG. 94.—Ternary System:
$MnSO_4$- Na_2SO_4–H_2O at 35°.
FIG. 95.—Ternary System:
$MnSO_4$- Na_2SO_4–H_2O at 25° (and 35°).

nearly the same, but the solubility of the double salt at 25° is rather less than it is at 35°. At 0°, 25°, and 35° the solubility of manganese sulphate is decreased by addition of sodium sulphate. This fact is of much greater interest on more particular examination, for the solid phases are different at the different temp. The decrease is least at 25°, where the solid phase is $MnSO_4.4H_2O$, and is greatest, being much accentuated, at 35°, where the solid phase is $MnSO_4.H_2O$. An intermediate decrease is shown at 0°, where the solid phase is $MnSO_4.7H_2O$. Thus, these isotherms show the effect of addition of sodium sulphate on the solubilities of the hepta-, tetra-, and monohydrated forms of manganese sulphate. The solubility of $MnSO_4.H_2O$ at 35° is slightly greater than that of $MnSO_4.4H_2O$ at 25°. At 0° and 25° the solubility of sodium sulphate is increased by the addition of manganese sulphate. At 35°, it is much decreased by increasing quantities of manganese sulphate. Here again there is a change of solid phase from the decahydrated to the anhydrous state.

A. and H. Benrath studied the ternary system Na_2SO_4–$MnSO_4$–H_2O at 97°. The following is a selection from the results for soln., where the proportions of sodium and manganous sulphates are expressed in percentages by weight; x denotes the mol. proportion of $MnSO_4$ in the mixture, and M, the number of mols. of water per mol. of the salt mixture:

MnSO$_4$	0	0·68	0·69	10·42	19·25	21·41	22·81	26·48	28·49 per cent.
Na$_2$SO$_4$	29·85	22·98	29·26	17·90	14·72	13·13	11·94	2·16	0 per cent.
x	0	2·10	2·16	35·40	55·14	60·48	64·22	92·05	100·00 per cent.
M	18·56	18·00	18·48	20·41	15·89	15·54	15·24	20·80	21·08

Solid phase : Na$_2$SO$_4$ 3Na$_2$SO$_4$.MnSO$_4$ Na$_2$SO$_4$.MnSO$_4$.H$_2$O   MnSO$_4$.H$_2$O

The results are plotted in Fig. 96—the dotted curve indicates sp. gr. The solid phases include the *dihydrate*, Na$_2$SO$_4$.MnSO$_4$.2H$_2$O, at 97°, and **sodium manganous tetrasulphate,** 3Na$_2$SO$_4$.MnSO$_4$.H$_2$O.
A. Benrath raised the question whether there is a limited region near 25° where the unstable tetrahydrate exists. For the stable region A. Benrath represented the equilibrium conditions of the ternary system at different temp. by Fig. 97.

A. Gorgeu prepared **sodium manganous oxytrisulphate,** Na$_2$SO$_4$.MnO. 2MnSO$_4$.4(or 5)H$_2$O, by a method similar to that employed for the ammonium salt, but at 100°; it is not certain if
FIG. 96.—Equilibrium in the System : MnSO$_4$–Na$_2$SO$_4$–H$_2$O at 97°.
FIG. 97.—Equilibrium Diagram of the Ternary System : Na$_2$SO$_4$–MnSO$_4$–H$_2$O at Different Temperatures.

the salt is isomorphous with the salts of potassium and ammonium. The oxysulphate loses its water of crystallization at 130°.

F. R. Mallet obtained **potassium manganous disulphate,** K$_2$SO$_4$.MnSO$_4$, in reddish-white tetrahedra, by fusing a mixture of the component salts. The crystals are stable in air. G. Carobbi and V. Caglioti could not prepare this salt; they always obtained the 1 : 2-salt, *vide infra*. G. Calcagni and D. Marotta studied the f.p. of mixtures of potassium and manganous sulphates. A compound potassium manganous trisulphate, K$_2$SO$_4$.2MnSO$_4$, is formed, but not the disulphate. The field b, Fig. 98, refers to liquid and solid soln. b ; c, to the liquid and the trisulphate ; d, to liquid and solid soln. ; e, to solid soln. b and the trisulphate ; f, solid soln. b and β-K$_2$SO$_4$; g, the trisulphate and the β-form of the component sulphates.

FIG. 98.—Freezing-Point Curves of the System : K$_2$SO$_4$–MnSO$_4$.

G. J. Mulder observed that a soln. saturated at 10° with manganous sulphate and then with potassium sulphate contains 44·3 parts of K$_2$SO$_4$, and 16·7 parts of MnSO$_4$ for 100 parts of water. According to J. C. G. de Marignac, the *dihydrate*, K$_2$SO$_4$.MnSO$_4$.2H$_2$O, is deposited in pale pink triclinic crystals from a soln. of equimolar parts of the component salts at 40° to 50°. G. N. Wyrouboff gave for the axial ratios of the triclinic crystals of the dihydrate $a : b : c$=0·7161 : 1 : 0·4482, and α=87° 50′, β=85° 36′, and γ=101° 29′. H. G. F. Schröder gave for the sp. gr. of the dehydrated but not fused salt, 2·954, and for the fused salt, 3·031.

R. M. Caven and W. Johnston's study of the ternary system K_2SO_4-$MnSO_4$-H_2O at 0° is summarized in Fig. 99. The tetrahydrated complex salt crystallizes as well at 0° as it does at 25°. The isotherm at 25° is similar to that at 0°, except that it shows a more rapid increase in the solubility of the manganous sulphate with additions of potassium sulphate up to the triple point. At 25° the tetrahydrate of manganous sulphate takes the place of the heptahydrate at 0°. The isotherm of

FIG. 99.—The Ternary System : K_2SO_4-$MnSO_4$-H_2O at 0°.
FIG. 100.—The Polytherms ot the System : $MnSO_4$-K_2SO_4-H_2O.

the potassium system at 0° is different from that of the ammonium system. The range of double salt formation is greater with the ammonium system, owing (i) to the greater solubility of ammonium sulphate, and (ii) to the fact that the complex ammonium salt is hexahydrated, whereas the potassium complex salt is tetrahydrated. J. I. Pierre, C. von Hauer, A. E. H. Tutton, and J. C. G. de Marignac obtained the *tetrahydrate*, K_2SO_4. $MnSO_4.4H_2O$, in pale pink monoclinic crystals by cooling to 0° a soln. sat. at ordinary temp., or by evaporating it in vacuo at 10° to 12°. The axial ratios are $a : b : c = 1.2485 : 1 : 1.0324$, and $\beta = 95° 0'$. R. Krickmeyer gave 2.234 for the sp. gr. at 20°; and H. G. F. Schröder gave 2.13 for the sp. gr., and added that the salt can be melted at a red-heat without decomposition. F. Ephraim and P. Wagner found the dissociation press. to be 400 mm. at 84.5°. J. Thomsen gave for the heat of soln. of $K_2Mn(SO_4)_2$, 6.38 Cals.; and of $K_2Mn(SO_4)_2.nH_2O$, when $n=1$, 1.76 Cals.; when $n=2$, -2.91 Cals.; when $n=3$, -4.60 Cals.; and when $n=4$, -6.435 Cals. The differences show that there are two definite stages in the hydration. J. Thomsen gave for the heat of forma-

FIG. 101.—The Ternary System : $MnSO_4$-K_2SO_4-H_2O between 0° and 100°.

tion $(MnSO_4,K_2SO_4,4H_2O)=13.8$ Cals., and for $(MnSO_4,K_2SO_4)=0.990$ Cal., while M. Berthelot gave 0.800 Cal. H. de Sénarmont found the index of refraction to be 1.487. E. Mitscherlich reported a *hexahydrate* of the type $K_2Mn(SO_4)_2.6H_2O$, corresponding with analogous compounds—the schönites—with magnesium, zinc, and iron; but J. C. G. de Marignac, and A. E. H. Tutton could not verify this. O. Aschan prepared the salt by the action of a soln. of potassium persulphate on
manganese. The subject was discussed by M. T. Salazar and E. Moles. A. Ben-
rath represented the equilibrium conditions and the phases in the ternary system
$MnSO_4$–K_2SO_4–H_2O, by Figs. 100 and 101. F. R. Mallet obtained **potassium
manganous trisulphate**, $K_2SO_4.2MnSO_4$, in pale red tetrahedra, by melting together
the component salts. The crystals are stable in air. G. Calcagni and D. Marotta's
curve, Fig. 98, shows the conditions of existence of this compound, which melts at
850°. G. Carobbi and V. Caglioti also found that a molten mixture of 2 mols of
manganous sulphate and a mol of potassium sulphate furnishes the 1 : 2 compound
corresponding with langbeinite, $K_2SO_4.2MgSO_4$; it is also formed when the com-
ponent sulphates are taken in equimolar proportions. The 1 : 2-compound was
found by F. Zambonini and G. Carobbi to occur in small pink tetrahedra in stalac-
tites of the lava cupola formed on Vesuvius in 1922. They called it **mangano-
langbeinite**. A. Gorgeu obtained **potassium manganous oxytrisulphate**,
$K_2SO_4.MnO.2MnSO_4.3H_2O$, by the process employed for the sodium salt. It is
isomorphous with the ammonium salt ; it loses its water of crystallization at 220°,
and when roasted it forms potassium and manganous sulphates and manganic
oxide. C. Montemartini and L. Losana studied the quaternary system
K_2SO_4–$MnSO_4$–H_2SO_4–H_2O, and they observed no evidence of the formation of
a quaternary salt. B. Gossner and T. Bäuerlein obtained a kind of *manganovolaite*,
$[KH_5(SO_4)_3]_2[(Fe,Al)_2(OH)_3][Mn(SO_4)_4].4H_2O$.

  G. N. Wyrouboff reported crystals of **rubidium manganous trisulphate**,
$Rb_2SO_4.2MnSO_4$, to be formed from a soln. of equimolar parts of the component

salts at 60° to 70°. F. R. Mallet obtained
reddish-white tetrahedra of **rubidium man-
ganous disulphate**, $Rb_2SO_4.MnSO_4$, from a
fused mixture of the component salts. The
crystals are stable in air, and are isomorphous
with the corresponding potassium and thallous
salts. A. Benrath's results are summarized in
Fig. 102. G. N. Wyrouboff obtained crystals
of the *dihydrate*, $Rb_2SO_4.MnSO_4.2H_2O$, from the
mother-liquor remaining after the separation of
the complex trisulphate. The rose-coloured
triclinic crystals have the axial ratios $a : b : c$

Fig. 102.—Equilibrium of Rubi-
dium and Manganous Sulphates.

$=0.8250 : 1 : 0.4412$, and $\alpha=89°$ 26′, $\beta=90°$ 28′, and $\gamma=108°$ 46′. Twinning
occurs about the (101)-plane. F. L. Perrot obtained crystals of the *hexahydrate*,
$Rb_2SO_4.MnSO_4.6H_2O$, from a soln. of the component salts. According to
A. E. H. Tutton, the habit of the monoclinic crystals of the hexahydrate is
tabular to short prismatic ; and the crystals have the axial ratios $a : b : c$
$=0.7382 : 1 : 0.4950$, and $\beta=105°$ 57′. The topic axial ratios are $\chi : \psi : \omega$
$=6.2542 : 8.4723 : 4.1938$. The optical character is positive ; and the optic axial
angles are :

	Li-line	C-line	Na-line	Tl-line	F-line
$2E$	109° 46′	109° 49′	109° 57′	110° 7′	110° 19′
$2V_a$	67° 10′	67° 8′	67° 5′	67° 1′	66° 55′

The apparent angle $2E$ for sodium light increases about a degree for 50° rise of
temp. F. L. Perrot gave 2·49 for the sp. gr. at 15° ; and A. E. H. Tutton found
2·459 at 20°/4°, and the mol. vol. 213·66. F. Ephraim and P. Wagner gave 211·2
for the mol. vol., and found the dissociation press. to be 400 mm. at 85·5°.
R. M. Caven and J. Ferguson found the vap. press. of the rubidium salt,
$MnSO_4.Rb_2SO_4.6H_2O$, to be in accord with log $p=-7.084+8419T^{-1}-1,781,000T^{-2}$.
F. L. Perrot measured the indices of refraction, and A. E. H. Tutton gave for
ordinary temp. :

	Li-line	C-line	Na-line	Tl-line	F-line	G-line
a	1·4741	1·4745	1·4767	1·4791	1·4821	1·4864
β	1·4781	1·4785	1·4807	1·4831	1·4860	1·4907
γ	1·4880	1·4884	1·4907	1·4933	1·4965	1·5015

so that the β-index reduced to a vacuum can be represented for wave-lengths λ as far as the F-line by $\beta=1\cdot4694+420{,}367\lambda^{-2}-491{,}200{,}000{,}000\lambda^{-4}$; and the α-index is reproduced by the same formula if $1\cdot4694$ be reduced by $0\cdot0040$, and the γ-index, if $1\cdot4694$ be increased by $0\cdot0100$. The indices at 70° are about $0\cdot0018$ less than those given in the table. The sp. refractions by the μ^2-formula are $0\cdot1145$, $0\cdot1153$, and $0\cdot1173$ respectively for α, β, and γ and the C-line; the mol. refractions are respectively $60\cdot14$, $60\cdot58$, and $61\cdot65$; and sp. dispersions, $\mu_G-\mu_C=0\cdot0024$, $0\cdot0025$, and $0\cdot0027$ respectively; and the mol. dispersions respectively $1\cdot29$, $1\cdot31$, and $1\cdot39$. The mol. refraction with the μ-formula are respectively $101\cdot47$, $102\cdot32$, and $104\cdot44$. The values are practically independent of temp. J. Locke found that 100 c.c. of water at 25° dissolve $35\cdot7$ grms. or $0\cdot0857$ mol of the salt.

A. E. H. Tutton prepared **cæsium manganous disulphate,** $Cs_2SO_4.MnSO_4.6H_2O$, by crystallization from a soln. of the component salts. The pale pink prismatic or pyramidal crystals are monoclinic with the axial ratios $a:b:c=0\cdot7274:1:0\cdot4913$, and $\beta=72°\,53'$. The $(\bar{2}01)$-cleavage is perfect. The topic axial ratios are $\chi:\psi:\omega=6\cdot3441:8\cdot7217:4\cdot2850$. The topical character is positive; and the optic axial angles at ordinary temp. are:

|	Li-line	C-line	Na-line	Tl-line	F-line
$2E$	97° 22′	97° 18′	96° 57′	96° 33′	96° 0′
$2V_a$	60° 10′	60° 7′	59° 57′	59° 46′	59° 28′

The angle $2E$ for sodium light diminishes about $2\cdot5°$ for a 50° rise of temp. The sp. gr. is $2\cdot7375$ at 20°/4°; and the mol. vol. is $226\cdot59$. R. M. Caven and J. Ferguson found the vap. press. of the cæsium salt, $MnSO_4.Cs_2SO_4.6H_2O$, to be in accord with log $p=2\cdot830+2236T^{-1}-830{,}860T^{-2}$. F. Ephraim and P. Wagner gave $226\cdot6$ for the mol. vol.; and found the dissociation press. to be 400 mm. at $8\cdot75°$. The indices of refraction are:

	Li-line	C-line	Na-line	Tl-line	F-line	G-line
α	1·4918	1·4922	1·4946	1·4972	1·5003	1·5046
β	1·4936	1·4940	1·4966	1·4991	1·5022	1·5066
γ	1·4995	1·4999	1·5025	1·5051	1·5083	1·5129

The β-index, in vacuo, can be represented for wave-lengths λ as far as the F-line by $\beta=1\cdot4803+722{,}115\lambda^{-2}-4{,}944{,}600{,}000{,}000\lambda^{-4}$; the α-indices are reproduced by the same formula by reducing $1\cdot4803$ by $0\cdot0019$; and the γ-indices, by raising $1\cdot4803$ by $0\cdot0019$. Measurements at 70° show that the index is lowered $0\cdot0018$ by a rise of temp. of 50°. The sp. refractions for the C-line and the μ^2-formula are $0\cdot1061$, $0\cdot1064$, and $0\cdot1075$ for α, β, and γ respectively; the mol. refractions for the C-line are respectively $65\cdot81$, $66\cdot01$, and $66\cdot68$; the sp. dispersions $\mu_G-\mu_C$ are respectively $0\cdot0022$, $0\cdot0023$, and $0\cdot0023$; and the mol. dispersions respectively $1\cdot40$, $1\cdot42$, and $1\cdot46$. The mol. refractions with the μ-formula are respectively $111\cdot62$, $112\cdot03$, and $113\cdot36$ for the C-line. The values are practically independent of temp. J. Locke found that 100 c.c. of water at 25° dissolve $8\cdot04$ grms. or $0\cdot157$ mol of the salt.

A. Étard reported **copper manganous disulphate,** $CuSO_4.MnSO_4.H_2O$, to be formed as a *monohydrate* from a conc. soln. of the component salts in the presence of a large excess of conc. sulphuric acid; and A. Scott, the *dihydrate*, $CuSO_4.MnSO_4.2H_2O$, in pale buff-yellow crystals, by adding sulphuric acid to a filtered soln. of the component salts. These salts are probably isomorphous mixtures. M. Schäuffele observed that manganous sulphate dissolves in a sat. soln. of copper sulphate, and conversely, and the soln. furnish isomorphous mixed crystals of varying composition. C. F. Rammelsberg noticed that a soln. with equimolar parts of pentahydrated copper sulphate and heptahydrated manganous sulphate yields triclinic crystals—the first crop of crystals has copper sulphate in excess, and the later crop, manganous sulphate in excess; while C. Weltzien observed that an isomorphous mixture of the form of pentahydrated copper sulphate is deposited from soln. with 12 times as much copper oxide as

manganous oxide. J. W. Retgers, working probably at 8° to 12°, observed that triclinic crystals, resembling pentahydrated manganous sulphate, are produced with 0 to 2·18 per cent. of pentahydrated copper sulphate ; with 5·11 to 38·52 per cent. of heptahydrated copper sulphate, pale blue monoclinic crystals are formed ; and with over 91·05 per cent. pentahydrated copper sulphate, the dark blue crystals are triclinic and resemble the pentahydrated copper sulphate. R. Hollmann observed that at 21° sat. soln. of the component salts in all proportions yield only feathery aggregates of triclinic pentahydrate. He measured the vap. press. of isomorphous mixtures of the two salts : with 0 to 16·1 per cent. of copper sulphate, the vap. press. is 13·4 to 11·8 mm. ; and with 77·4 to 100 per cent. of copper sulphate, the vap. press. is 3·7 to 5·8 mm. W. Stortenbeker found that at 18° the penta-hydrate $(Cu,Mn)SO_4.5H_2O$ is formed with 0 to 10·5 and 22·9 to 100 per cent. penta-hydrated copper sulphate ; and the heptahydrate $(Cu,Mn)SO_4.7H_2O$ with 16 to 23·5 per cent. of copper sulphate. At 21°, however, a continuous series of iso-morphous mixtures of the pentahydrate is formed—Fig. 103. Below 25° the hydrates—monoclinic $MnSO_4.7H_2O$ and $CuSO_4.7H_2O$, as well as triclinic $MnSO_4.5H_2O$ and $CuSO_4.5H_2O$—are involved. Let $m7$ denote monoclinic $(Cu,Mn)SO_4.7H_2O$, and $t5$, triclinic $(Cu,Mn)SO_4.5H_2O$, and R. Hollmann's observa-tions are summarized in Fig. 104, at 0°, and Fig. 105, at 17°. The decomposition and formation of isomorphous mixtures furnishes three types of curve in which

FIGS. 103, 104, and 105.—Isomorphous Mixtures of Copper and Manganous Sulphates.

the decomposition temp. for any mixture (i) lies between those of the components —e.g. mixtures of the heptahydrates of zinc and manganous sulphates ; (ii) reaches a maximum value—e.g. the heptahydrates of copper and manganous sulphates ; and (iii) has a minimum value. According to A. Recoura, a mixture of copper hydroxide and a cold aq. soln. of manganous sulphate furnishes green flocks of the composition copper manganous oxysulphate, $24CuO.MnSO_4.nH_2O$; and with a boiling aq. soln. of manganous sulphate, greyish-green flocks of $3CuO.MnSO_4.$ nH_2O. A. Mailhe obtained $2CuO.MnSO_4.3H_2O$ from copper hydroxide and a boiling aq. soln. of manganous sulphate of medium concentration. The green isomorphous powder is dehydrated at 200° to 250°. A. Werner likewise obtained what he called the hexol salt, $3Cu(OH)_2.MnSO_4$. H. Vohl studied the isomorphous mixtures of copper sulphate and ammonium manganous sulphate.

In opposition to G. Klatzo, J. W. Retgers found that the beryllium manganous sulphates crystallize separately from a mixed soln. at 25°, in the form of the tetra-hydrates. P. B. Sarkar and N. Ray prepared ammonium beryllium manganous fluosulphate, $(NH_4)_2BeF_4.MnSO_4.6H_2O$. According to C. F. Rammelsberg, when a mixed soln. of magnesium manganous sulphates is evaporated, a crop of colourless crystals of the magnesium salt first appears ; the second crop of crystals has a reddish colour. The first crop contains an excess of magnesium sulphate, and the second crop an excess of manganous sulphate. A doubtful mineral from Herrengrund, Hungary, was described by A. Breithaupt, and called fauserite—after M. Fauser. The reddish-

or yellowish-white crystals are grouped in stalactitic forms; the brachypinacoidal cleavage is distinct; the prismatic cleavage is faint or absent; and the basal cleavage distinct. The analyses of J. Molnar correspond with $(Mg,Mn)SO_4.6H_2O$, with the ratio $MnO : MgO$ approximately $20 : 5.5$ by weight. The sp. gr. is 1·888 and the hardness 2·0 to 2·5. According to R. Ballo, and M. H. Hey, fauserite is an isomorphous mixture of magnesium and manganous sulphates, for when a mixed soln. of the component salts is allowed to crystallize between 18° and 21°, isomorphous mixtures with all proportions of the two components can be obtained. R. Hollmann said that only one series of triclinic crystals is formed, probably of the pentahydrate. H. Vohl obtained isomorphous mixtures of **ammonium magnesium manganous sulphates,** and of **potassium magnesium manganous sulphates.** Hydrated manganous sulphate was shown by C. F. Rammelsberg, W. Storten-beker, etc., to form several series of isomorphous mixtures with hydrated zinc sulphate, although the individual salts between 0° and 39° do not form isomorphous hydrates. Thus, R. Hollmann, and R. Sahmen showed that while monoclinic heptahydrated manganous sulphate passes at about 8·8° into triclinic pentahydrate, and at about 26·6° into rhombic tetrahydrate; and rhombic heptahydrated zinc sulphate at about 38·75° forms the monoclinic hexahydrate, yet the complex series of isomorphous mixtures of the **zinc manganous sulphates** indicated in Figs. 106 to 110 is formed at the temp. indicated. Here $r7$ refers to rhombic $(Zn,Mn)SO_4.7H_2O$; $m7$, to monoclinic $(Zn,Mn)SO_4.7H_2O$; $m6$, to monoclinic $(Zn,Mn)SO_4.6H_2O$; $t5$, to triclinic $(Zn,Mn)SO_4.5H_2O$; and $r4$ to rhombic $(Zn,Mn)SO_4.4H_2O$. R. Hollmann studied the decomposition of the isomorphous
FIGS. 106 to 110.—Isomorphous Mixtures of Zinc and Manganous Sulphates.

mixtures—*vide supra*. The mineral **mooreite** from Sterling Hill, New Jersey, described by L. H. Bauer and H. Berman, is clear glassy and white, and has the composition $7R(OH)_2.RSO_4.4H_2O$, where $R=Mg : Mn : Zn=4 : 2 : 1$; and δ-**mooreite** is bluish-white, with the composition $6R(OH)_2.RSO_4.4H_2O$, where $R=Mg : Mn : Zn=5 : 3 : 4$. Mooreite is monoclinic, with a perfect cleavage parallel to (010) ; the hardness is 3 ; and the sp. gr. 2·470. The optical character of the biaxial crystals is negative ; the optic axial angle $2V=50°$; and the indices of refraction $\alpha=1.533$, $\beta=1.545$, and $\gamma=1.547$. Granular δ-mooreite has an imperfect cleavage; the hardness is 3 ; and the sp. gr. 2·665. The optical character of the biaxial crystals is negative ; the optic axial angle $2V=40°$; and the indices of refraction $\alpha=1.570$, $\beta=1.584$, and $\gamma=1.585$. H. Vohl reported the formation of **ammonium zinc manganous sulphate,** $2(NH_4)_2SO_4.ZnSO_4.MnSO_4.12H_2O$; **potassium zinc manganous sulphate,** $2K_2SO_4.ZnSO_4.MnSO_4.12H_2O$; and **magnesium zinc manganous sulphate,** $MgSO_4.ZnSO_4.MnSO_4.21H_2O$.

A mineral from Lagoa Bay, South America, was regarded by J. Apjohn as a *manganous alum* and called by E. F. Glocker **apjohnite**—after J. Apjohn. It also occurs in Alum Cave, Tennessee. Its composition, according to analyses reported by J. Apjohn, R. J. Kane, H. Ludwig, W. G. Brown, and C. F. Rammelsberg, approximates **manganous aluminium sulphate,** $MnSO_4.Al_2(SO_4)_3.24H_2O$, but this result is probably influenced by an attempt to emphasize the analogy with the alums. R. M. Caven and T. C. Mitchell found the conditions of stability of this compound, $Al_2(SO_4)_3.MnSO_4.22H_2O$, at 30° to be those indicated in Fig. 111; it occurs as a solid phase in acicular crystals, between the aluminium sulphate and

manganous sulphate curves. Apjohnite occurs in transparent needles with a silky lustre, and they are thought to be monoclinic; it also occurs in fibrous or asbestos-like masses, and as crusts or efflorescences. Its colour is white with a faint tinge of rose, green, or yellow. The sp. gr. is 1·782, and the hardness 1·5. It tastes like ordinary alum. A related *magneso-manganous alum* occurs in a cube near the Bushman (Bosjesman or Boschjesman) river, South Africa, and it is hence called **bushmanite**, or *boschjesmanite*, *bosjesmanite*, or *buschmannite*. Analyses reported by F. Stromeyer, J. L. Smith, and G. A. Kenngott agree with the formula for **magnesium manganous aluminium sulphate**, $(Mg,Mn)SO_4.Al_2(SO_4)_3.22$ or $24H_2O$. There is also a similar mineral from Maderanerthal, Switzerland, and called **keramohalite**. It also occurs at Alum Point, Utah. L. D. Gale at first regarded the Utah mineral as a manganous alum.

FIG. 111.—The Ternary System : $Al_2(SO_4)_3$–$MnSO_4$–H_2O at 30°.
FIG. 112.—The Equilibrium of Thallous and Manganous Sulphates.

F. R. Mallet melted a mixture of manganous and thallous sulphates in equimolar proportions, and obtained reddish-white, cubic crystals of **thallous manganous disulphate**, $Tl_2Mn(SO_4)_2$. A. Benrath's results are summarized in Fig. 112. According to F. R. Mallet, the disulphate is stable in air. A. E. H. Tutton obtained well-defined crystals of the *hexahydrate*, $Tl_2Mn(SO_4)_2.6H_2O$. The holohedral, monoclinic prisms have the axial ratios $a:b:c=0.7454:1:0.4964$, and $\beta=106° 22'$. The cleavage is parallel to the (001)-face. The topic axial ratios are $\chi:\psi:\omega=6.2134:8.3357:4.1378$. The topic axial angle $2E$ was not measurable in air, but $2V_a$ had the values :

	Li-	C-	Na-	Tl-	Cd-	F-line
$2V_a$	71° 14'	71° 16'	71° 26'	71° 41'	71° 49'	71° 59'

The sp. gr. is 3·685 at 20°/4°; and the mol. vol. 205·62. The indices of refraction are :

	Li-	C-	Na-	Tl-	Cd-	F-line
a	1·5820	1·5826	1·5861	1·5900	1·5927	1·5959
β	1·5954	1·5960	1·5996	1·6035	1·6063	1·6096
γ	1·6041	1·6047	1·6084	1·6123	1·6152	1·6186

The general formula for β is $1.5786+832324\lambda^{-2}-310540000000\lambda^{-4}+\cdots$ and the formula applies for the a-index if 1·5786 be reduced by 0·0135; and for the γ-index if 1·5786 is increased by 0·0088. The sp. refractions with the μ^2-formula are 0·0906, 0·0923, and 0·0934 respectively for the a-, β-, and γ-rays; likewise for the mol. refraction by the μ^2-formula respectively 68·68, 69·96, and 70·79 ; and by the μ-formula respectively 119·80, 122·55, and 124·34—the mean value being 122·23. By heating manganic chromic sulphate, A. Étard obtained a green powder of what he regarded as **manganous chromic sulphate**, $MnSO_4.Cr_2(SO_4)_3$. There are also complexes of manganous sulphate with ferric sulphate (*q.v.*), and isomorphous mixtures with ferrous sulphate (*q.v.*).
